THURSDAY, SEPTEMBER 2, 1915.

THE EXAMINATION OF HYDROCARBON OILS.

The Examination of Hydrocarbon Oils and of Saponifiable Fats and Waxes. By Prof. D. Holde. Authorised translation from the fourth German edition by Prof. E. Mueller. Pp. xv + 483. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 21*s*. net.

THE important part played by liquid fuel, both for steam raising and in the internal combustion motor, has focussed a large amount of attention upon the examination of hydrocarbon oils for commercial use, whilst the many "cracking" processes that have been introduced to supplement the supply of the lighter fractions of petroleum for motor purposes have considerably increased the interest felt in the somewhat involved actions, partly analytic and largely synthetic, that under the influence of heat and pressure bring about such profound changes in the characteristics of the oils.

Under these conditions any book dealing with the analysis of such oils would have been welcomed, and Dr. Holde has made the fourth edition of his work on the examination of hydrocarbon oils more attractive and at the same time more useful by introducing chapters on the tars obtained by the distillation of coal, lignite, shale, and peat, on saponifiable fats and the technical products prepared from them, and on waxes.

The first chapter occupies more than half the book, and deals with petroleum and petroleum products. After touching upon the occurrence, chemical composition, and formation of petroleum, there is an excellent section on its physical examination, followed by one on its chemical treatment, in which the flash-point is apparently given as the measure of the inflammability of the oil, the paragraph being headed "Inflammability," whilst a few pages later another paragraph is devoted to "Burning Point." The chemist knows perfectly well what is meant by flash and burning points, but the non-initiated, when told that naphtha has a flash point of $-21°$ C. and a burning point of $-19°$ C., gets an uncomfortable feeling that the material is too inflammable to have anything to do with, and before it is possible to clear up properly the muddlement that these terms have created it will be necessary to determine the igniting points of the various hydrocarbons present in petroleum, which vary from 400° C. to 700° C.

In dealing with the calorific value of naphthas for internal combustion motors the reader is told that "it is determined in a bomb," but no details are given as to how the dangers and difficulties of such a determination with a highly volatile spirit are to be got over. In discussing Hensler and Engler's combustion method for the determination of sulphur in oils, the dweller in a manufacturing town will be amused to read that since the laboratory air often contains sulphur, the tubes to supply the air for combustion are led into the open air; as 10 to 12 grams of oil are burnt in five hours, the sulphur from the air of even London would amount to more than the oil probably contained.

In many technical applications the book is scarcely up to date; for instance, we are told that "an attempt has been made" to cover the surface of roads with tar or oil, and later, "the tar applied hot is brushed into the street." The reader is also informed on p. 44 that "the gasoline used in pleasure vehicles should have no more than 5 per cent. of those components which boil

above 100° C., since otherwise the engine will frequently misfire"; considering that Pratt's spirit usually gives a little under 60 per cent., distilling below 100° C., and many petrol substitutes considerably less, this seems a misleading statement.

On p. 45 we are told that "the vapour pressure must be considered in storing naphtha and other inflammable liquids," but it is now being recognised that the determination of this factor is also of the greatest importance in forming a sound conclusion as to the ease of starting and flexibility in running with a motor spirit, as the amount of vapour given off at atmospheric temperatures governs the formation of the explosive mixture in the cylinder when starting from cold.

Directions are given for determining the vapour tension by introducing the petrol into the Torricellian vacuum above the barometric column in a 10 mm. diameter tube, but a far more simple and practical method is to use the pressure tube devised by Sir Boverton Redwood and Captain Thomson, which is adopted for testing the pressures developed in vessels containing petrol.

Several pages are devoted to the viscosity of oils and testing their lubricating value, and also to the setting point and fluidity of oils, their value for gas-making and tendency to resinification.

The book is, like most of the technical works of German origin, a model of abstracting, and invaluable as giving full references to original work, but its utility is discounted in the laboratory by the absence of practical detail.

Chapter ii. is devoted to natural asphalt, and contains much useful information on the subject; chapter iii. deals with ozokerite and Montan wax; whilst in chapter iv. we come to the important subject of the tars obtained by the distillation of coal, lignite, shale, and peat.

The attention devoted to the recovery of the coal-tar products in Germany led one to hope that this part of the book would contain much valuable information, but unfortunately the subject is not treated very fully, and points of such importance as the differences in tars due to variations in the temperature of carbonisation receive but scanty notice, whilst the use of the products of tar distillation is dismissed with the curt remark that "these are of great importance in the preparation of dye-stuffs and of pharmaceutical products." It might have been expected that special attention would have been devoted at the present time to the detection, estimation, and purification of those tar products used in the production of high explosives, but even the fact that it is the source of the most important explosives of the day is not mentioned.

The saponifiable fats and their technical products are a very useful section of the book, which ends with a chapter on waxes. Prof. E. Mueller is to be congratulated on the translation of the original German work, and the type, illustrations, and general style are of the excellence always found in Messrs. Wiley's technical publications.

ELECTRICAL ENGINEERING.

(1) *Continuous-current Electrical Engineering.* By W. T. Maccall. Pp. viii+466. (London: University Tutorial Press, Ltd., 1915.) Price 10*s.* 6*d.*

(2) *Single-phase Electric Railways.* By E. Austin. Pp. xiv+303. (London: Constable and Co., Ltd., 1915.) Price 21*s.* net.

(1) MR. MACCALL'S book is well above the standard usually found in books which cover such a wide field, and it can be thoroughly recommended, both to engineers and to students. To the latter, the large selection of questions will be of especial value. The book covers the ground indicated by its title about as thoroughly as could be expected in a volume of its size and price; the most noteworthy omission is the subject of primary batteries. More might have been said about electric heating, a little about electric cooking, and electric furnaces might at least have been mentioned.

The chapters on illumination and lamps are very good indeed, and contain little that we would wish to alter. But those on machines, although quite up to the standard of most text-books, are certainly less satisfactory. Here and there the matter is rather weak. Thus the portion dealing with generator characteristics does not show that real grip of the subject which an instructor ought to have. Another point is the geometry of the armature winding diagrams. A developed diagram is shown with the poles behind, the commutator *below,* and the numbers running from left to right; while a radial diagram has clockwise rotation of the numbers. These are not consistent with one another.

We do not think the author has ever tried to separate the no-load losses of a machine in any of the ways he has described, or we should have seen some doubts expressed as to the validity of some of them. In fact, he would probably have found, as we ourselves once did, that the "friction" alone, as determined from the constant speed experiment, *exceeds* the "friction+hysteresis" given by the constant flux experiment. In short, this method won't work, for it assumes that the frictional torque is the same at all speeds, which is very far from the truth. The running down test can be carried out much more simply than in the manner described, and it can be modified

so as to give a complete analysis of the losses in about half an hour after getting the machines into a steady condition.

We are flattered by the graceful acknowledgment that our mode of numbering the illustrations has been adopted, but we would have greatly preferred that in a much more important direction the author had followed the methods we advocate, but cannot claim to have originated. We refer to the practice of making the algebraic symbols stand for *things* and not merely for numbers, so that the formulas will apply irrespective of units. Mr. Maccall seems unable to discuss principles apart from some particular units, with the result that his mathematics is horribly complicated by numbers which have nothing to do with the facts, but arise from the unfortunate, although perhaps customary, choice of units. In some cases we are treated to separate deductions of formulas for inch and metric measure, instead of one formula with two sets of constants. As we said on a former occasion, the laws of nature were exactly the same ages before man ever discovered anything about them, much less invented units in which to express his measurements concerning them. *Make the symbols stand for things and the units will look after themselves.* Formulas will then represent *facts*, and not merely particular numerical relations.

We like the author's special symbol for "number of turns," but we object to making his other new symbol do double duty by using it both for "current × turns" and for the name of the unit "ampere-turn."

For the new edition, which we confidently expect, we hope that the publishers will adopt a paper suitable for reproducing the half-tone blocks. Fortunately, these form only a small proportion of the illustrations, but where they do occur they entirely spoil the appearance of the book, while at the same time they are seldom sufficiently distinct to be of any real use.

(2) "Single-phase Electric Railways" gives an outline description, with leading data, of all the important lines of this type which have so far been constructed. Although most of the matter has already been published in the columns of the *Engineer,* it is convenient to have it all collected together for ready reference. For that reason, it is unfortunate that the author has decided not to deal fully with the motor itself, and also that he has not included a great deal more data regarding the operating costs, of which much has been made public during the past few years.

The book is abundantly and well illustrated by drawings and photographs; indeed, the latter take such a very prominent place as to almost form the *raison d'être* of the book. The overhead construction is taken in fairly full detail, but the particulars of the motors and controlling gear are somewhat meagre. Diagrams of connections are certainly there, but the written description is generally too slight, except for the expert.

The first chapter of three pages is mainly historical, but just touches on the thorny battle of the systems. More eloquent than all the opinions of the author and the experts is the fact, brought out in a recent number of the *General Electric Review*, that since the advent of the high-voltage continuous-current system, the mileage of single-phase railways has been practically stationary, while that of the continuous-current system has gone up by leaps and bounds, and now far surpasses its rival. It would have been far better if this chapter had given an account of the general principles underlying single-phase railway working, and a closely reasoned account of the difficulties arising from it, the way in which these have been overcome, and the relative advantages and disadvantages of the system. A comparison of the solutions found for these difficulties in the various lines described further on would have served to weld the book into a homogeneous whole, instead of leaving it in twenty-three water-tight compartments (one for each line described), with no connection between them but the common title to the whole book.

We may conclude by saying that to the expert and to the student of railway engineering, the book will be of especial value as a work of reference, diminished although that is by the lack of references to other publications. Others may find it interesting, for the style is good and the matter is made as readable as a catalogue (for such it really is) well can be.

DAVID ROBERTSON.

THE LIMITATIONS OF SCIENCE.

(1) *The Limitations of Science.* By Prof. L. T. More. Pp. vii + 268. (New York: H. Holt and Co., 1915.) Price $1.50 net.

(2) *The Magic of Experience.* A Contribution to the Theory of Knowledge. By H. Stanley Redgrove. Pp. xv + 111. (London: J. M. Dent and Sons, Ltd., 1915.) Price 2s. 6d. net.

(1) PROF. MORE has written a study from a conservative point of view of the limitations of science as shown in modern physical views. "Will the results of experiment made objectively which must, however, be interpreted subjectively, fail in their turn as criteria of truth?" (p. 2). "Science, . . . like philosophy, has no ontological value. Should not the men of science clearly recognise this fact, and confine

their effort to the legitimate function of science—the discovery of natural phenomena and their classification into general laws by logical mathematical processes?" (p. 31).

The account of the growth of the mechanistic view in science and of atomism, and the criticism of them and development of a science of energetics by Rankine, Mach, Duhem, and Ostwald, are fairly adequate, and direct attention to some points—notably in Rankine's attitude—which have been forgotten by most people. It is rather disappointing to find no mention of Stallo's extremely important work in the theory of knowledge, especially when we see that the second chapter is headed "The Metaphysical Tendencies of Modern Physics," and read such passages as that on p. 70. But Prof. More's problem is not quite the same as Stallo's. In Stallo's time physicists vigorously denied that their theories had a metaphysical basis, and it was Stallo's purpose to show that the physicists were mistaken in their denial. But at the present time such a theory as Larmor's has an avowedly philosophical background. The great obligation of modern physics to Descartes is seen from the admirable discussion of Descartes' physical system in chapter iii. "A comparison of his [Descartes'] postulates and conclusions with those of our modern theory shows them to be almost identical, if we change his antiquated knowledge and his discarded metaphysical language into modern terminology" (p. 67; *cf.* pp. 98, 101).

The fourth chapter is a reprint of an article in the *Philosophical Magazine*, and, under the heading "The Scientific Method," contains a very sensible critical review of recent physical theory. Prof. More himself advances a hypothesis to make the ratio e/m agree with the experimental evidence (p. 140). The fifth chapter is on "The Classical and the New Mechanics," and here Prof. More concludes that, if we finally adopt the most modern thesis that matter is the manifestation of energy, we are acknowledging that "the guides to knowledge are now to be found in those subjective impressions which must depend on the individual, and vary with him. . . . The classical natural philosophy of Newton and Galileo has drifted into that transcendental symbolism which is apt to take place when German thinkers become the leaders in philosophy" (p. 163). The sixth chapter is on "Skepticism and Idolatry in Science," and here some of the writings of Poincaré and Sir Oliver Lodge make admirable illustrations; and the seventh chapter is on "Science as the Arbiter of Ethics." This is a thoughtful book, and though easy to read, is not superficial.

(2) Mr. Redgrove's book makes a great point of the fact that experience is subjective, as Berkeley pointed out, and of which Mach has made such illuminating use in physics. Of course materialism becomes easily refutable from this point of view. Mr. Redgrove leans to the mysticism of John Smith the "Cambridge Platonist," Boehme, and Swedenborg, but—and this would surprise some after that—he adopts what seems to be a very sensible attitude in his emphasis on the validity of the laws of nature, and the fallacy of "Christian Science" metaphysics. Mr. Redgrove follows Mill in thinking that mathematical truth is merely founded on experience, and holds that absolute truth is unknown and unknowable. In spite of this we may approach truth, "just as a mathematical series may for ever progress towards some limit which it never reaches" (p. 86). The mathematical illustrations seem to be quite irrelevant: we might just as well illustrate a fanciful doctrine that we can attain the limits of knowledge over and over again in our lives, and yet approach no definite knowledge, by instancing the function sin x as x proceeds to infinity along the real axis. ϕ.

RECENT ELECTRICAL BOOKS.

(1) *Arithmetic of Alternating Currents.* By E. H. Crapper. Pp. vii+208. (London: Whittaker and Co., 1915.) Price 2*s.* 6*d.* net.

(2) *Constant-voltage Transmission: a Discussion of the Use of Synchronous Motors for Eliminating Variation in Voltage in Electric Power Systems.* By H. B. Dwight. Pp. vii+115. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 5*s.* 6*d.* net.

(3) *Alternating-current Work: an Introductory Book for Engineers and Students.* By W. P. Maycock. Pp. xxiii+415. (London: Whittaker and Co., 1915.) Price 6*s.* net.

(4) *Experimental Electricity and Magnetism.* By M. Finn. Pp. x+436. (London: G. Bell and Sons, Ltd., 1915.) Price 4*s.* 6*d.*

(1) PROF. E. H. CRAPPER'S book can be recommended to all desiring to obtain a thorough working knowledge of the everyday calculations which have to be made by alternating-current engineers. The lengthy experience the author has had in training electrical engineers has convinced him that the only way to master the subject is to acquire facility in solving the types of numerical problems which occur in practice. There are 232 examples in the book. The answers to all of them are given, and fifty are worked out in full. They are arranged in order of difficulty, and none of them make excessive demands on the

knowledge or ability of the student. We have tested the numerical accuracy of the answers given to several of the problems with satisfactory results.

(2) Mr. H. B. Dwight is the electrical engineer to the Canadian Westinghouse Company, and is one of the greatest authorities on long-distance power transmission. To the reader conversant with the technicalities of electrical engineering this book can be warmly recommended. The author points out the advantages of using special synchronous motors to keep the voltages at the distributing stations constant under all conditions of load. By this means the radius of action of electric power transmission can be very considerably increased. The main advantage gained by this increase of distance is that it renders possible the linking together of large networks either directly or by suitable "frequency transformers." The economies rendered possible by this procedure are well known and much thought about by electrical engineers. Unfortunately the main difficulties in linking up all the supply companies in London have to do with the vested interests concerned and the inherent conservatism of station engineers.

In America there are several large networks already in existence. In North and South Carolina, for instance, over a thousand miles of 100,000-volt transmission lines are now linked together, the lines stretching across 800 miles of country. The Pacific Gas and Electric Company of California has a network of 1500 miles, part of it being at 60,000 and part at 100,000 volts. It is highly probable that even this extended supply of "electricity in bulk" will seem quite small in a few years' time, as some of the many schemes projected for linking up systems of electric railways are sure to be carried out. Mr. Dwight's book, therefore, discusses a problem of great commercial and economic value. In discussing the more technical side of the problem Mr. Dwight uses complex hyperbolic operators, and has been successful in considerably simplifying the usual treatment.

(3) Mr. W. Perren Maycock's book is intended as an introduction to alternating-current work. The diagrams are beautifully clear, the apparatus described is all useful and fundamental, and the descriptions are good. Simplified vector diagrams are given. Many will find this work useful as an introduction to more advanced treatises.

The defects of the book are due mainly to an attempt to explain to the non-mathematical reader certain steps in the proofs of physical theorems which demand mathematical knowledge. Unless these steps are proved rigorously it does not seem worth while to give them. No proof, for instance, is given that when the voltage follows the harmonic law its effective value equals 1·11 times its average value. To assume this, and to point out in reasoning backwards that

$$1{\cdot}11 = 0{\cdot}707/0{\cdot}636 = \pi/(2\sqrt{2}),$$

is rather a futile proceeding. It would be better to state definitely that the value 1·11 used by the designer of alternating-current apparatus is approximately equal to $\pi/(2\sqrt{2})$, which is the value deduced theoretically from the properties of the sine curve.

(4) From the point of view of the teacher, the chief merit of Mr. Finn's book is its thoroughly practical nature. Assuming that the physical laboratory is fitted with the electric light, he shows that many excellent and instructive experiments can easily be arranged for junior students. The student will appreciate the notes on heat and dynamics which are freely interpolated throughout the text. The introduction and explanation of technical terms in common use are innovations which are to be commended. Everyone should know what is meant by an adapter, a wall-plug, a kilowatt-hour, bayonet and screw cap lampholders, etc. We think also that all teachers should know what is meant by "earthing," and that one of the mains of the supply company is usually earthed. Electrical students have generally very hazy notions about what is meant by the potentials of the supply mains. They seem to have acquired at school the notion that difference of potential is the only thing that need be considered, and that the absolute value of the potential is of no consequence. A good teacher could easily explain the fallacy of this by pointing out how workmen sometimes get dangerous shocks owing to neglect of certain very elementary precautions.

In one or two places the author's experiments are perhaps too elementary. For example, it seems unnecessary to prove that the currents in conductors in parallel are not always equal to one another. In some places the wording is clumsy. On p. 374, for instance, instead of saying "the bigger is the dielectric strength said to be," it would be better to say "the greater the electric strength." We are told that the "dielectric constant" of a medium "varies somewhat with the length of time for which the E.M.F. is applied." Whether this is true or not depends on how we define the dielectric constant. It certainly varies with temperature. Everyone must perforce admit that it is not a constant. It seems foolish, therefore, for physicists to go on calling it a constant. The terms inductivity, dielectric coefficient, and S.I.C. are in use. There is no excuse therefore, for using the word "constant" for a variable quantity.

After defining the electrostatic unit of potential,

the author goes on to say that "it follows" that the electrostatic unit $= 3 \times 10^{10}$ A.E.M.U.'s of E.M.F. $= 300$ volts. It would be a phenomenal beginner who was able to follow this reasoning without further explanation. A. RUSSELL.

OUR BOOKSHELF.

Overcrowding and Defective Housing in the Rural Districts. By Dr. H. B. Bashore. Pp. 92. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 4s. 6d. net.

WE are apt to associate overcrowding and defective housing with towns in the "old" countries, but it is well to realise that a condition of things as bad or worse may exist in our rural districts and in new settlements. In this little book Dr. Harvey Bashore, an inspector in the Pennsylvania Department of Health, describes conditions of overcrowding and defective housing which exist in his own district. He deals with the subject under four headings: (1) land overcrowding; (2) house overcrowding; (3) defective buildings; and (4) overcrowded and defective schools.

Instances of these various conditions, illustrated by well-reproduced plates, are given, and the results are summarised in a concluding chapter. The latter are exactly the same as in the great cities—lack of efficiency, disease, and premature disease to many—"while the great majority of people subjected to overcrowding and bad housing do not prematurely die, yet they have a lessened physical and mental vigour and are less able to do properly their daily work, and not only become a loss to themselves and their families, but to the State; and for ever stand on the threshold of that dread disease—tuberculosis; for tuberculosis is the one great disease of the overcrowded." As regards the remedy, Dr. Bashore says: "This problem cannot be attacked, as in the great cities, by legislative enactment or resort to legal measures, but the solution lies in proper education by the health authorities, by the schools, and by the Press, and the crusade must be kept up until the people understand that it pays—pays in real dollars and cents—to live in sanitary homes."

Although written from the American view-point, we would commend this little book to the notice of councillors, landlords, and health visitors in this country. R. T. HEWLETT.

Typical Flies. A Photographic Atlas of Diptera, including Aphaniptera. By E. K. Pearce. Pp. xii+47. (Cambridge: At the University Press, 1915.) Price 5s. net.

THIS volume contains four pages of introduction, with instructions for collecting and for setting specimens of flies caught, Brauer's Classification of Diptera (four pages), and 155 reproductions in half-tone of photographs of fleas and flies. Its aim is to be of service to the beginner and to draw attention to the interest of an order of insect that is much neglected.

The photographs are as good as any we have seen of this class of insect—a peculiarly difficult class to represent pictorially in any natural manner; the venation of the wings is well brought out wherever the banding or colouring of the wings does not obscure it, and there are excellent short notes as to habitat, larval habits, and so on under the pictures. We wish it had been possible to provide under the photographs line drawings of the more important types of venation and of some of the antennæ; but the interest taken in this group is so little that we imagine further expenditure on the volume was impossible.

The diversity of appearance is well brought out; to the student the venation systems depicted will be helpful, and to the beginner the variety of habitat and habit will be distinctly stimulating.

Probably no order of insect will so well repay the collector and investigator in this country, and we hope this volume may stimulate a wider interest in this fascinating group. H. M.-L.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Destruction of Wasps.

YOU may be interested to know that whilst starting up a motor-cycle a few days since, I accidentally discovered that benzol sprayed over a wasp instantly killed it. I tried the same experiment with petrol with the same result.

Knowing of two nests in the neighbourhood I went that night and with a small oil gun injected two or three ounces of benzol into each nest. In the morning I found the two nests entirely destroyed.

Next night I visited an open nest which had been partly destroyed by another means, and in which several hundred wasps were still living. They covered an area as large as a cheese plate, and on lighting them up showed signs of activity. One squirt full of petrol was hastily sprayed over them, and the whole lot were instantly killed.

This method is so safe, simple, and effective that I feel it should be generally known. The petrol or benzol acts entirely by vaporisation and produces asphyxiation. It is not fired in any way.

A. H. MITCHELL.

Horn's Green, Knockholt, Kent, August 24.

Atlantic Oceanic Currents.

A LARGE bell-buoy was cast ashore at Porto Santo, the northern island of the Madeira group, in the early days of March in the present year.

I have ascertained that the buoy came from Pearl Reef, Magdalen Islands, in the Gulf of St. Lawrence, having broken adrift from its moorings in the autumn of 1912, occupying thus two years and a half in transit. These facts are important at a time when our accepted notions of the strength and direction of the Atlantic currents are undergoing revision.

It may be remembered that Christopher Columbus, who resided at Porto Santo, and married a daughter of Peristrello, the Governor in those days, derived his inspiration and dream of lands beyond the sunset from the arrival of seed-pods and other suggestive matter drifting in upon the broad current which bathes these rocky shores. MICHAEL C. GRABHAM.

Madeira, August 19.

THE BRITISH ASSOCIATION MEETING IN MANCHESTER.

THE meeting of the British Association in Manchester will provide a busy week for those who choose to avail themselves of the opportunities provided for scientific discussion and visits to places of special interest. As previously announced, the long-distance excursions that old members are accustomed to on the afternoon of the Saturday and on the last Wednesday of the meeting will not be found on the programme, but the executive committee has arranged for a large number of visits to the principal municipal undertakings, works, and warehouses, which should prove to be of exceptional interest. Most of these visits will be made in the afternoon, and will not therefore interfere with the important work of the sections. It is difficult to select from the list any one that may be regarded as especially noteworthy because there is so much variety offered by the great industrial community of which Manchester is the centre, and an appeal to many different interests will be made. But as the Manchester Ship Canal is sometimes regarded as one of the wonders of the world, it is probable that the visit to the Manchester docks and canal will be one of the most attractive features. This visit will take place on the afternoon of Friday, September 10, and the party will be limited to one hundred. The Ship Canal Company has kindly provided a special steamer for the visitors, and arrangements will be made for the inspection of all the principal engineering features of this great undertaking.

The important works of the Manchester and of the Salford electricity departments will be shown to small parties in the course of the three working days of the meeting, and opportunities will be afforded for members and associates to visit the corporation gas works, water works, and sewage disposal works. Of the visits to the works of the principal Manchester industries that to the Pilkington Tile and Pottery Co. at Clifton Junction will probably be one of the most interesting; but the most ambitious so far as distance is concerned is the proposed visit to the soap works of Messrs. Lever Bros. at Port Sunlight on Thursday, September 9.

Other visits that may be specially referred to are to the works of the cotton spinners, of several large electrical machinery manufacturing companies, of the great Manchester warehouses, of the hat manufacturers of Stockport, of the calico-printers, of the packing warehouses, etc.

In connection with the special work of the sections several excursions on a small scale have been arranged. Thus, Section C (Geology) will adjourn in the afternoons for visits to places of geological interest in the immediate neighbourhood for field demonstrations of Dr. Hickling's paper on the geology of Manchester, and there will be a longer excursion arranged for the Saturday afternoon. Section D (Zoology) will adjourn to the zoological laboratories on Thursday afternoon for exhibits and demonstrations of original work that has been conducted or is in progress in the university. Section E (Geography) proposes an afternoon excursion into Derbyshire. Section H (Anthropology) proposes a visit to the Roman camp at Ribchester, on which occasion Sir F. F. Adam will preside. For Section K (Botany) a series of interesting demonstrations in the botanical laboratories of the university are being arranged; and Section L (Educational Science) has arranged for two visits to educational institutions, one, on Thursday afternoon, to the Kindergarten Training College in Whalley Range, when Sir William Mather will entertain the party to tea, and the other to the school for feeble-minded children at Sandlebridge.

On Wednesday evening the Lord Mayor of Manchester will hold a reception in the Manchester School of Technology from 8 to 8.30, after which members and associates will be able to inspect the workrooms, machinery, and appliances of the institution.

Every effort is being made by the local executive committee to ensure the success of the meeting, and although it cannot be expected that the numbers will be as large as they would have been in normal times, there is every prospect of a good attendance of men of science and of important work being done.

ART AND CRAFT IN FISHING.[1]

IN recent years the contemplative man seems to have changed his nature, to judge from some of the books which he gives to the world. Time was when he was content just to go fishing, with the simple object of catching fish. But now his demeanour is more that of a man who is setting out on a serious piece of scientific work, and, though he has not quite lost what Francis Francis used to call "a kind of prejudice for a brace of fish in the creel," he is mighty particular as to how that brace of fish got there. Should he, so to say, have been overtaken in inadvertency and have decoyed one of them in a manner not permitted to the elect, his conscience will know many pangs, and likely his tongue will begin the story with apology and end with explanation. There is no longer pride in a fish just as a fish. The modern achievement is a fish caught on a female olive. The same fish caught on an Alexandra would be like a shot fox; for the angler has become a much improved and superior person, and (may we confess it?) at times a little difficult to live with.

His literature, however, has certainly gained in interest, because it can no longer be said, as it used to be said, that there is nothing new to be written about fishing. The mere discovery of the female olive brought a whole new world swimming into one's ken. And since then there have been

[1] (1) "Fly-Fishing: Some New Arts and Mysteries." By J. C. Mottram. Pp. xii+272. (London: *Field* and *Queen* (Horace Cox), Ltd., n.d.) Price 5s. net.

(2) "The Complete Science of Fly Fishing and Spinning." By Fred. G. Shaw. Pp. xiii+432. (Published by the Author, Neville Court, Abbey Road, N.W., 1914.) Price 21s.

other developments to give the angler a still more earnest countenance, such as the discovery that a fish's life-history is written on its scales, or that you may capture a chalk-stream trout with a wet fly, not as of old empirically, but with due regard to all the laws of science, and in a manner to command the admiration of the impartial.

(1) Dr. Mottram's little book is an excellent sample of the newer fishing writing, in which various old problems are approached in the spirit of scientific inquiry, solutions being offered in a way that inspires confidence. The author is evidently a good and very zealous angler, he has had a scientific training, and he does both experimenting and thinking for himself. He seems singularly free from the common angling tendency to take other people's experience for ascertained fact, which gives his conclusions, even in matters on which others have written with authority, a value of their own. He treats of a great diversity of subjects, of water weeds and their merits as food-producers (here, though generally sound and useful, he is too sweeping; for instance, he condemns *Elodra canadensis* out of hand, which seems strange; it is horribly free in its growth, but it is far from being a bad weed otherwise); of the colour sense of fish, citing a very interesting and careful experiment, which showed a roach to have a sense of colour; of optical problems. which are about the latest of the fly-fisher's studies, adding something to our ideas; of waterside fly-tying, the treatment of mud, fish watching, difficult casts, and so on. He gives several chapters on his own sport, especially in New Zealand, where he seems to have been about the first angler to study natural flies and imitate them.

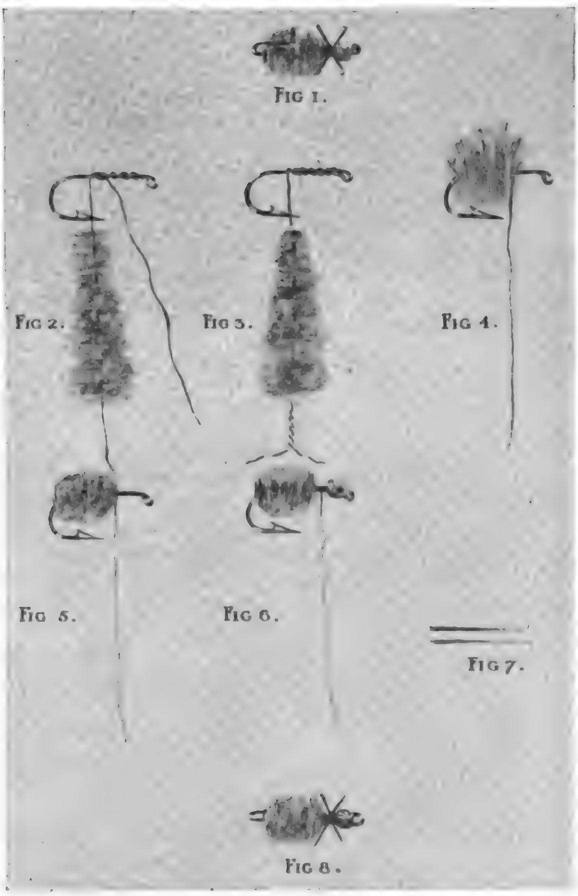

FIG. 1.—The tying of a new fancy fly. From "Fly-Fishing: Some New Arts and Mysteries," by J. C. Mottram.

This brings us to what is certainly the most important part of Dr. Mottram's book, his theory of imitation of flies, which is unfolded in a chapter entitled "Flies of the Future." He breaks boldly away from the exact imitation school with its tradition of stiff opaque wings for floating duns, and substitutes what might be called a policy of impressionism, in which he lays special stress on the shape of a fly's body and on methods of obtaining the transparent effect which is so defiant of imitation in the natural dun. The idea that "one of the best ways of indicating transparency is to omit the transparent parts altogether," is extremely ingenious, and it should work out well in practice. Ingenuity is, indeed, a marked feature of the whole book, which is a valuable addition to the fishing library.

(2) Mr. Shaw's book is a more ambitious volume, as its rather formidable title would indicate. The "complete science"—it is a big aim. In one respect, however, Mr. Shaw seems to us to justify his selection of the title. There is probably no angler of the day who has so carefully studied what may be called the dynamics of fishing, the various ways of getting a fly or spinning bait to a given point in the most effective manner. Mr. Shaw's chapters on casting show a remarkable grasp of principles, the exposition of which will teach even the oldest hands a lot. Most anglers—even very good—cast their fly or bait without any very clear notion how they get the results they aim at. They know these to be fairly satisfactory and do not trouble further. Mr. Shaw shows exactly what happens when you do certain things with your rod, and proves conclusively why it must happen. Also he suggests many other things which you may do, things of which you have very likely never thought, and which are bound to be extremely useful to you. Wind casts, Wye casts, steeple casts, Galway casts, loop, switch, and Spey casts—there are many devices by which you can get the better of difficulties. With excellent photographs and diagrams Mr. Shaw expounds them all, and if it is possible for a man to learn technique from the printed page—and it certainly is possible for some—he should gain a great deal from this book.

In the other portion of the volume he deals partly with the practice of fishing and partly with various matters, more or less scientific, in which the angler takes an interest. He is obviously a good fisherman as well as a good caster (the two are not necessarily complements of each other), and he is full of useful hints and contrivances such as an expert picks up in many years of fishing.

For instance: "Use the two tops of your fly-rod alternately," he advises, and the advice is very obviously sound. But some of us, alas! have never thought of it before, regarding the second top as merely a spare one for emergencies. And yet we have talked to each other with conviction about split cane getting "tired" after continuous use for some time! This is a small matter, but there are plenty of similar casual hints which will come forcibly home to a good many of us who have long passed out of our novitiate.

In the other chapters Mr. Shaw deals with the fisherman's entomology, now a fairly well-ploughed field, with pisciculture and the natural history of trout, of which much the same may be said, now that there is a trout farm in almost every likely valley of springs, with the senses of trout, particular attention being paid to their vision, and especially to how far they can see behind them, a point which so far as we remember

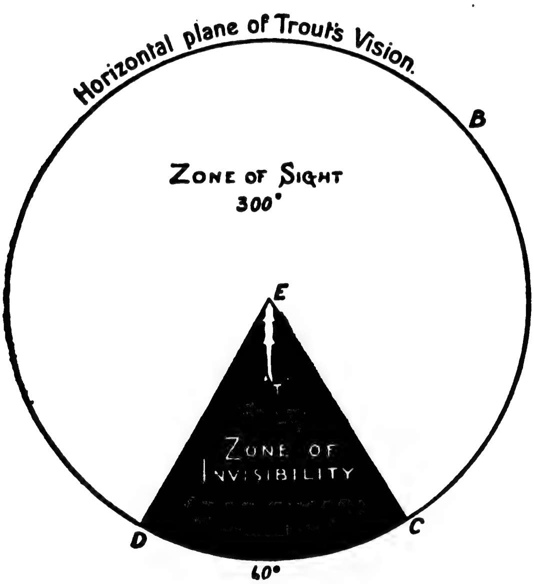

FIG. 2.—From "The Complete Science of Fly Fishing and Spinning," by F. G. Shaw.

no other writer has tackled—but it is one of importance, as every man who has stalked a fish on a "shy" day will allow.

There are also chapters on salmon and salmon scales. In the last Mr. Shaw devotes a great many words to labouring what seems to us an odd objection to the usual interpretation of what is called the spawning mark, which is, of course, that a fish has spawned in some previous year. Mr. Shaw apparently wants evidence of the act itself before he will admit that salmon ever spawn more than once. The spawning mark, in his view, would, we gather, be evidence of a visit to fresh water for the purpose of spawning, but not necessarily that the purpose was satisfactorily accomplished, the ova being duly fertilised and safely stored in the redds. So far nobody would quarrel with him, we expect, but, unless we wrong him, he seems to find in the spawning mark evidence that the spawning purpose has *not* been carried out, the eggs being voided in vain or re-absorbed. A fish so cheated "will return again and again until it has satisfactorily achieved its life's purpose." We fear we cannot produce scales from a fish marked in the act of spawning and recaptured later, to convince Mr. Shaw. Perhaps he can produce scales from the necessary percentage of unfortunate fish which have been found voiding their ova in vain to convince us? At present our inclination is towards the current view of the spawning mark and its significance. There are other points in the book in which our view would not coincide with Mr. Shaw's (incidentally we have found some scarcely excusable misprints), but on the whole we must own to having studied him not without pleasure and profit.

THE TESTING OF CHRONOMETERS.[1]

IN his recently issued report on the testing of chronometers at Geneva, M. Raoul Gautier, who has been in charge of the department for twenty-five years, takes the opportunity of reviewing briefly the successive alterations and improvements that have been introduced in the methods of testing, and the happy results that have followed from the maintenance of a high standard. We may take this same opportunity of congratulating the distinguished director of the observatory on the useful work accomplished, and with which the name of Gautier has been so long and so honourably connected.

Nearly a century has passed since Alfred Gautier combined the duties of the director of the observatory with those attached to the Chair of Astronomy. But even before that time Geneva was bidding for the watch trade and fully alive to the advantage that would accrue from an increase in the accuracy of performance. In 1789 prizes were offered by the local Society of Arts for a notable improvement in the rate of pocket watches, but the prize remained unawarded, for the ambitions of the judges were so much in advance of the abilities of the maker that the standard was not attained. In framing more modest requirements, it was stipulated that the daily rate of the watch should not vary more than one minute during a trial of a month in a vertical and horizontal position, and not more than two minutes when worn for the same period. Two watches were submitted, and one was stated to have fulfilled the conditions.

These were humble beginnings, and the disturbed state of Europe during the Napoleonic wars prevented anything like an annual competition, which the local Society of Arts proposed to hold. But progress must have been rapid, for in 1816 the limit of variation of rate was reduced to three seconds in twenty-four hours, whether the watch was at rest or carried in the pocket. For the first time we find a temperature factor mentioned: the watch was to be kept in a constant temperature of 25° Réaumur, and it was not till much later that any serious attempt was made to remove the ill

[1] "Rapport sur le Concours de Réglage de Chronomètres." Par M. le Prof. Raoul Gautier, Directeur de l'Observatoire de Genève.

effects of varying temperature on the rate of pocket watches.

The main fact to be noticed in connection with these early trials is that they settled the lines on which future tests have been made. The qualities demanded now are, as they were then, smallness of daily rate, uniformity of rate in different positions of the balance, and constant rate within a considerable range of temperature. The number of variables is small, and wherever chronometer testing is carried on, little change has been made in the manner of conducting the test. Details vary at different observatories, but one general practice is pursued. For a certain number of days constituting "a period," the watch is kept in a vertical position with pendent up, or to the right, or left, and horizontally, with dial up or down. Further the watch is submitted to varying temperature, generally covering about 50° F. in the whole, and throughout the several "periods" the daily rate is determined by comparison with a clock regulated to Greenwich Mean Time. The relative excellence of the instrument tested in shown by assigning marks for its performance in each period, and herein there is room for the exercise of individual judgment in deciding relative merit. One authority may consider the elimination of temperature effects of more importance than smallness of rate, and give higher marks accordingly. To secure accurate adjustment for "positions" may seem to some the most desirable qualification.

M. Gautier hints that steps might be taken with advantage to secure greater uniformity among different observatories. But the system of awarding marks is of no great importance, for a good watch comes so near perfection that it will take nearly the maximum of marks, however they are divided. M. Gautier remarks that a comparison between the trials at Kew and Geneva shows that the results are in close agreement, and that this conclusion is warranted is proved by the fact that the best watch at Geneva, tested by the Kew system of marks, would have 95·9, while the best at Kew was assigned 96·1 marks.

At Geneva, to within the last few years, the total number of marks that could be earned was 300, of which 100 were assigned to steadiness of daily rate (m); 100 to uniformity of rate in different positions (p); 70 for excellence of temperature compensation (c); and 30 for smallness of variation (r) throughout the test. At the same time limiting values are assigned to m, p, c, and r, which may not be exceeded without loss of certificate. These several maximum values are shown in the expression from which is computed the number of marks to which the watch is entitled.

$$N = (0^{s}{\cdot}75 - m)\,400/3 + (2^{s}{\cdot}50 - p)\,40 + (0^{s}{\cdot}20 - c)\,350 + (5^{s}{\cdot}00 - r)\,6.$$

If any one of these terms is negative the watch fails to meet the test, but it can be withdrawn, corrected by the maker, and re-submitted to test in those particulars in which it failed, but the opportunity of competing for the highest places in competitive tests is denied to such watches. Later, the number of marks was increased to 1000, but the two scales are not directly comparable, for the conditions of test have been made more severe. The variation from daily rate must not exceed 0·5 sec. in any one test, the rate in different positions is reduced from 2·5 sec. to 2·0 sec., and in other respects the demand for greater accuracy is on the same scale.

It is gratifying to know that the improvement in manufacture has more than kept pace with the requirements for test, and that M. Gautier is able to report that the highest excellence yet attained was exhibited by the chronometers of 1914. This also is the experience of Kew, where of sixty-two watches submitted to trial, forty-eight were awarded more than 90 per cent. of the maximum marks. Of even greater significance is the increasing certainty of manufacture. The writer of this article has long held that after a certain high standard has been reached, the maker must depend upon some lucky accident for pre-eminence. He is unable to explain the cause of superiority, and though he may take equal care he cannot repeat his success. But when we find that the Kew record is held by M. P. Ditisheim, of Chaux-de-Fonds, with a score of 96·1, and the same maker is able to secure the first four places in a competition of unusual severity, it is evident that chance is fast being eliminated. Such improved workmanship demonstrates the success that has attended the scheme of annual competition, originated with the view of encouraging the Swiss watch manufacture. The number of watches submitted for test is not large, about 200 per annum, but a healthy competition has raised a high standard of excellence, and taught the public what to expect.

Besançon leads the way in France. The method of test varies slightly from that of Geneva, but the details only concern the expert. The point we would make is that such establishments are eminently useful and instructive. By advertising widely what has been accomplished they make the public dissatisfied with inferior workmanship, and they offer opportunities for the careful maker to gain recognition for his work. A standard of accuracy is set up that encourages the public distribution of time signals, and promotes a smoother working of national life.

FREDERICK MANSON BAILEY, C.M.G.

THE death of Frederick Manson Bailey, C.M.G., the veteran Colonial Botanist of Queensland, which was announced in the last issue of NATURE, will be felt as a great loss to Australian botany. He inherited his botanical tastes from his father, John Bailey, who emigrated to South Australia in 1838, the family having conducted the business of nurserymen and seedsmen in London for many years. F. M. Bailey helped his father for a time in the nursery business at Adelaide, which he established on resigning the position of Government botanist—to which post he was appointed on his arrival in South Aus-

tralia—but he did not seriously take up horticulture again until he landed at Brisbane in 1861 after a spell of gold-digging in Victoria and farming in New Zealand. He then established a seed business in Brisbane, a venture, however, attended with no great measure of success owing to financial conditions in Queensland, but his real opportunity came in 1875, when the Queensland Government appointed a committee to inquire into diseases affecting live stock and plants, and he was chosen to investigate the botanical problems involved. In connection with the duties of this appointment he travelled far and wide throughout the State, and gained that extensive knowledge of the flora of Queensland which enabled him to make his numerous and valuable contributions to Queensland botany.

His earlier work was mainly connected with the native grasses of Queensland, which formed the subject of many articles valuable to the botanist and agriculturist alike. He was next appointed to the charge of the botanical section of the Queensland Museum, and in 1881 was made Colonial Botanist, the post which he held until his death. The duties of this post, which were very congenial to him, he discharged with conspicuous ability and untiring devotion, and, during the times of depression when the post was abolished, he continued his work unpaid until, as a result of general protest, he was reinstated in his former position.

The distinction of C.M.G. conferred upon him in 1911 was a fitting recognition of the value of his botanical and agricultural services to Queensland. His contributions to botany embrace the purely systematic as well as the economic aspects of the subject. Another subject to which he paid particular attention was the medicinal uses of plants.

Among his more important publications must be mentioned "The Flora of Queensland" in seven volumes; "The Handbook of the Ferns of Queensland"; a sketch of the "Economic Plants of Queensland"; "Plants reputed Poisonous and Injurious to Stock"; "Queensland Woods"; "Queensland Grasses," etc.

Bailey also devoted much time and attention, especially in later years, to the study of fungi and algæ, and until a few days before his death he was a regular contributor of critical specimens to the National Herbarium at Kew, which has been greatly enriched, as regards the Queensland flora, by the specimens he so generously presented.

NOTES.

WE see from the Transactions of the Royal Scottish Arboricultural Society (of which he is the honorary editor) that Dr. A. W. Borthwick, lecturer in forest botany in the University of Edinburgh, has been appointed by the Board of Agriculture for Scotland to be the advisory officer of the Board for forestry in succession to the late Dr. John Nisbet.

WE learn that the nineteenth International Congress of Americanists, which was to have been held in Washington in October next, and which was postponed in consequence of the war, is, according to present arrangements, to take place at Washington on December 27–31 next, in conjunction with the anthropological section of the Pan-American Scientific Congress, the American Anthropological Association, the American Historical Association, the American Folklore Society, and the Archæological Institute of America.

THE autumn meeting of the Iron and Steel Institute will be held at the Institution of Civil Engineers on September 23 and 24, when the following papers may be expected to be read and discussed:—Influence of oxygen on some properties of pure iron, W. Austin; note on the carburisation of iron at low temperatures in blast-furnace gases, T. H. Byrom; influence of heat-treatment on the specific resistance and chemical constitution of carbon steels, Prof. E. D. Campbell; effect of chromium and tungsten upon the hardening and tempering of high-speed tool-steel, Prof. C. A. Edwards and H. Kikkawa; phosphorus in iron and steel, Dr. W. H. Hatfield; the magnetic transformation of cementite, Prof. K. Honda and H. Takagi; sulphur in malleable cast-iron, R. H. Smith; iron and nitrogen, Prof. N. Tschischewski.

THE council of the Iron and Steel Institute gives notice that at the forthcoming meeting of the institute the following new rule for addition to the existing by-laws will be submitted:—"In the event of a state of war existing between Great Britain and any other country, or State, all members, honorary members, and honorary vice-presidents who shall be subjects of such enemy country, or State, shall forthwith cease to be members, honorary members, or honorary vice-presidents of the institute, but they may, if the council thinks fit, be reinstated after the termination of the war."

THE Royal Aero Club announces that the British height record for pilot alone has been granted to Mr. H. G. Hawker, the National Physical Laboratory having reported that the barograph and chart used by the aviator on June 6 showed that the height attained was 18,393 ft. The previous best record was that of 14,920 ft., accomplished by Eng.-Lieut. E. F. Briggs, now a prisoner in Germany.

WE deeply regret to record the death in action at the Dardanelles, on August 10, of Second Lieut. H. G. J. Moseley, Trinity College, Oxford, son of the late Prof. H. N. Moseley. Lieut. Moseley was formerly lecturer and demonstrator in physics at the University of Manchester, and holder of the John Harling fellowship for research.

WE much regret to learn that Capt. T. P. Black, 9th Sherwood Foresters, registrar of University College, Nottingham, was killed at the Dardanelles between August 7 and 11. He was for a time assistant in physics at the Durham College of Science, Newcastle-upon-Tyne, removing in 1907 to University College, Nottingham, to fill a similar position. In 1911 he was appointed registrar of the college.

WE note, with regret, the death, on August 28, at the age of fifty-six years, of Mr. Henry Crookes, the eldest son of Sir William Crookes. He was an asso-

ciate of the Royal School of Mines, and a fellow of the Chemical Society.

The death is announced of Lieut.-Col. Edward Lawrie, M.B., I.M.S. (ret.), at the age of sixty-nine. Col. Lawrie was educated at Edinburgh University, and after acting as house surgeon to Prof. Syme, whose views probably largely influenced his subsequent work on chloroform anæsthesia, he entered the Indian Medical Service, from which he retired in 1901. During his career he held the posts of resident surgeon of the Medical College Hospital, Calcutta, acting for some time as professor of physiology in the Medical College, professor of surgery in the Lahore Medical College, and residency surgeon at Hyderabad, one of the most important medical appointments in India. He was best known for his views on anæsthesia, being an ardent advocate of the claims of cholorform to be the best and safest anæsthetic for general use. Lawrie held, with his old teacher Syme, that chloroform killed only through the respiration, and not through the heart. As many held the converse opinion, Lawrie prevailed upon the Nizam of Hyderabad to institute and finance a commission to investigate the subject, of which commission Sir Lauder Brunton was president and Col. Lawrie and the late Sir Gerald Bomford were members. Much experimental work was done, which confirmed Lawrie's views, the monkeys dying without exception from failure of respiration, and a valuable report was published; he was also the author of "Chloroform: A Manual for Students and Practitioners" (1901). When the hospitals for the Indian troops were opened at Brighton in December last, Lawrie was appointed anæsthetist, and carried out his duties until the beginning of his fatal illness last May.

Lieut. Ernest Magowan Harper, 7th Batt. Munster Fusiliers, who was killed in action on August 9, at the Dardanelles, was a graduate of Queen's University, Belfast. He was educated at the Royal School, Dungannon, where he gained a reputation for brilliant work, and received his training as a keen sportsman, which afterwards characterised him at the University. On matriculation he entered Queen's with a junior science scholarship, which he held throughout his undergraduate course. In 1913 he graduated bachelor of science with first-class honours in chemistry, and afterwards was appointed to the Andrews research studentship, which he held until the time of his death. During his tenure of this scholarship he conducted extended researches on the connection between the absorption spectra and the constitution of organic nitro-compounds, publishing two papers in the Journal of the Chemical Society. On the declaration of war he applied for a commission and was gazetted last September, being posted to the 7th Munster Fusiliers. He relinquished his post of senior assistant in chemistry in the University, abandoned his scientific career, and gave himself up unselfishly for his country's cause. In his death the country has lost an able officer, and science a most promising young man.

Lieut. Wolfred Reeve Cloutman, R.E., who was killed in action in France on August 21, was an associate of the Royal School of Mines, obtaining his associateship in mining (first class) in 1912, after winning many prizes and completing a most distinguished career at the school, where his death is felt as a serious loss. Mr. Cloutman's work at the Royal School of Mines (an integral part of the Imperial College of Science and Technology) was further recognised by the award to him of the diploma of membership of the Imperial College. On leaving the school Mr. Cloutman was awarded a scholarship by the council of the Institution of Mining and Metallurgy for a post-graduate course in mines or works in various parts of the world. In 1914 the governors of the Imperial College awarded to him the Warrington Smyth prize and medal for a report which he submitted on certain mining operations in Western Australia. As a mining engineer Mr. Cloutman was valuable to the Army, and in June last he was mentioned in despatches for his skill and success in mining operations.

The death is announced, at the age of forty-nine years, of Dr. R. W. Johnstone, a medical inspector of the Local Government Board. Dr. Johnstone had been British delegate at the International Health Office, Paris, a member of the Commission for the Investigation of Mediterranean Fever, chief technical delegate for Great Britain at the International Sanitary Conference at Paris, 1911–12, and plenipotentiary to sign the International Sanitary Convention of Paris in 1912.

The death is reported, in his sixty-fourth year, of Dr. Thomas Bliss Stillman, an American chemist, who had spent the greater part of his career on the staff of the Stevens Institute of Technology, New Jersey. From 1886 to 1903 he was professor of analytical chemistry in that institution, and from 1903 to 1909 professor of engineering chemistry. He was the author of "Engineering Chemistry," first published in 1897, and of various monographs in American and European scientific journals.

Many of our readers, especially among those who attended the meeting of the British Association at Winnipeg in 1909, will be grieved to hear of the death of Mrs. W. H. Thompson, who has recently succumbed to an attack of appendicitis. Mrs. Thompson was an active member of the committee responsible for the arrangements of the Winnipeg meeting. She was for some years a contributor to the work of the Ductless Glands Committee, and published an important paper on the thyroid gland (Phil. Trans., 1910), in addition to contributions to the Trans. of the Royal Society of Canada and other journals. For some years Mrs. Thompson was librarian of the University of Manitoba, and her loss will be keenly felt in academic circles in Canada.

Mr. Bernard Kettle, curator of the Guildhall Museum, reports some interesting finds of Roman pottery from dust-heaps in the City of London. A large series of these was disclosed when the old General Post Office in St. Martin's-le-Grand was demolished. A few whole pots and many fragments of Samian ware were found here, besides building

materials, whetstones, beads, knives, coins, and other small objects. Most of these rubbish-pits date between A.D. 50 and 200, and by comparison of datable with undatable specimens much light has been thrown upon the seriation of types. From another rubbish-pit in King William Street nine Samian vessels of the first century have been reconstructed, one of them being a vessel finer than any hitherto found in London, and two specimens of a type hitherto unknown in England. These were associated with a lamp, two coins, and other pottery and bronze objects.

THE novel discovery in the Fayum of a nephrite celt is announced by Mr. Oric Bates in the September issue of *Man*. This specimen is remarkable because its greatest width is not, as in the common Fayum type, along the cord of the cutting edge. The material is a sort of nephrite, composed of minute fibres of actinolite, and in its present form it is of metamorphic origin. The source whence the stone may have been obtained is at present uncertain, and it is impossible to say whether this development of actinolite is due to regional metamorphism or contact metamorphism. At any rate, the rock can only have come from some region where there has been extensive metamorphism of one kind or another.

AN important monograph on the genus Sansevieria, the source of bow-string hemp, occupies seventy-six pages of the current number of the *Kew Bulletin* (No. 5). The account is by Mr. N. E. Brown, who has made a lifelong study of this difficult and highly important economic group of plants. The paper is illustrated by a series of text figures representing the salient features of the different species, and there are two plates of a new species, *S. Dawei*, from Uganda. Fifty-four species in all are described in detail, and a full key is provided which should be of great value in running down the plants. In order that the paper may be of use to the planting community, in whose interests it has largely been prepared, the few technical terms employed are fully explained at the beginning. Africa is the true home of the genus, and East Africa in particular, where it is an important economic product. Only four species are known to occur outside Africa, and they are found in Ceylon, India, Burma, and possibly China. Of the fifty African species only five are natives of South Africa, the rest being confined to the tropical area of the Continent. As considerable doubt still exists as to which species yields the best fibre, it is hoped that the publication of the monograph may help to bring about a solution of so important a question.

BOTANICAL specimens are commonly deprived of all beauty, and much of their value, by the loss of colour in the flower-heads. This very serious drawback has now been removed by the timely discovery of a method of colour-preservation by Dr. C. F. Fothergill, and described in detail in the *Museums Journal* for July. It has the further merit of extreme simplicity. Briefly, Dr. Fothergill employs sheets of absorbent cotton wool, placed in three layers forming two compartments between two "grids," which are made of a "wire mesh-work of half-inch squares with a heavy encircling band." The necessary pressure is obtained by fastening one or two straps, preferably of webbing, around the grids, and tightening them as required. The flowers to be pressed, having been placed in the grid, are then suspended in front of a fire, or in the sun, when this is sufficiently powerful. The explanation of the success of the method is, that the process of drying is so rapid that the pigment is fixed instead of being slowly decomposed. Fresh carnations can be preserved in about seven hours. Primroses picked fresh off the living plant can be permanently dried to retain a lifelike colour in two hours if the press containing them is placed in the oven.

THE first part of vol. v., section 2, of *Flora Capensis* has now appeared, having been prepared at the Herbarium of the Royal Botanic Gardens, Kew. The families dealt with are the Thymeleaceæ, 181 species in twelve genera; the Peneaceæ, 24 species in five genera; the Geissolomaceæ, with the single monotypic genus Geissoloma; the Loranthaceæ, consisting of 42 species in two genera; and the Santalaceæ. This last family, which contains six genera in South Africa, is completed as far as the 112th species of Thesium in the present part.

PROF. G. S. BOULGER has published in the form of a pamphlet, price one penny, his paper on the History of Kew Gardens, read before the South-Eastern Union of Scientific Societies. The paper, though covering a well-explored field, contains several interesting particulars about the early history of the Royal Gardens. A letter from Gilbert White to Robert Marsham about Stephen Hales, written in 1791, which is reproduced, presents a very vivid picture of that ingenious physiologist's versatility in all forms of experiment. The history is brought down to the present day, and an outline of the functions of Kew is given in conclusion.

AT the last monthly general meeting of the session of the Zoological Society of London, his Grace the Duke of Bedford in the chair, it was announced that two Californian sea-lions had been added to the menagerie of the society, thus partially repairing the loss by disease sustained some time ago. Two tortoises, new to the collection, were received on deposit on July 18. One of these is the blackish tortoise (*Testudo nigrita*) from Indefatigable Island, the other Bauer's tortoise (*T. galapagoensis*) from Charles Island. The receipts in gate-money for July showed a decrease of 724*l.* as compared with July of last year. The receipts for admission at the gates during the present year—to the end of July—showed a decrease of 274*l.* as compared with the corresponding period during the last ten years. Having regard to the times, this falling-off in receipts is less than might have been expected.

THE *National Geographic Magazine* for August should attain a phenomenal sale, if only on account of its illustrations, which include no fewer than eighty coloured figures of American game birds, by Louis Fuertes. Both from the point of view of scientific accuracy and artistic merit these are as near perfec-

tion as is humanly possible. These illustrations accompany an article on American game birds, by Mr. Henry Henshaw, which should be seriously studied by every field naturalist and sportsman in the British Islands; for the author draws a by no means exaggerated picture of the ravages inflicted by modern firearms on birds of real economic importance, and the need for drastic legislation to prevent their speedy extermination. And there can be no question but that his contentions have their roots deep down in solid fact. In a second article, describing the impressive transformation in the physiography of the country affected by the formation of the huge lake in the Gatun region, during the construction of the Panama Canal, Mr. George Shiras draws a vivid picture of the destruction of animal and plant life which has been inevitable but none the less regrettable. Thickly forested valleys teeming with animal life have now been converted into one vast lake. But the author holds that this area should be converted by the Federal Government into a reservation for the absolute protection of the survivors from this deluge. In course of time, he points out, if this is done, water-fowl of all kinds will find sanctuary here, and serve as a "feeder" for the areas depleted by the sportsman.

IN his presidental address, read at the American Association of Museums, San Francisco, Dr. O. C. Farrington gave an able summary of the origin and evolution of natural history museums, which should be widely read in this country. More especially is this to be urged in view of the danger which threatens such institutions in the immediate future in regard to the policy of national retrenchment which is now in process of formation. There is a danger that the pruning-hook may be used too ruthlessly, thereby inflicting material harm. For reformers are generally enthusiasts, and therefore are to be carefully watched, experience having shown that a sense of proportion is not usually among their attributes. Museums, as he remarks, are even now commonly regarded as a luxury, but he leaves no uncertainty as to the vitally important part which the modern museum plays, and must continue to play, in ever-increasing force, in our national life: widening our outlook and conceptions of existence, and affording to the uninitiated sources of information as to the nature of disease and pestilence, and other aspects of economic zoology which are indispensable to the speeding up of progress and well-being.

IN *La Nature* for August 21, 1915, L. De Launay shows the extent of the recent discoveries of coal-bearing strata in Germany, Belgium, and the Netherlands. Though the ultimate ownership of some of these stores may seem uncertain, there is no doubt as to their importance in the economy of Europe. The explorations have proceeded at depths from 1000 to 1500 metres (nearly 5000 ft.). The Westphalian coalfield has thus been connected with that of south-east Belgium, through the tracing of intermediate fields between Wesel and Aachen. On the east side of the Rhine, moreover, from Essen to Wesel and Haltern, the Westphalian basin has been proved to have a vast extension. West of the Meuse, and south of the innocent lands of Nijmegen, Holland participates in the new discoveries. At the Dutch frontier the coal is within 300 metres of the surface. Since 1901, the Belgian field has been traced far northwards beneath the Cainozoic strata of Limbourg between Brussels and Maastricht, and away west into the province of Antwerp. The results in northern France have been less important, but the total coal resources of the areas dealt with in M. De Launay's article are double those that were known a few years ago. The author cannot resist a suggestion that, "after the war," France should annex the basin of the Saar.

DR. A. WADE's researches on "The Supposed Oil-bearing areas of South Australia" have been published as Bulletin No. 4 of the Geological Survey of the State. Its wise conclusions and scientific thoroughness recommend this report as a model to be followed by explorers. The remarks about those superficial observers who stimulate unprofitable enterprises by saying that "the country is exactly like such-and-such an oilfield" should be read by financial magnates as well as by would-be prospectors.

IN the fifth volume of the Journal of the Natural History and Science Society of Western Australia (Perth, 1914, price 2*s*. 6*d*.), C. G. Thorp (p. 20) reviews the interesting glassy bodies known as Australites, and gives a useful map of their distribution. He regards them as ejected from a volcano or volcanoes in the East Indies, some of them in Tertiary and some in modern times. The blebs of glass now found were attached to bubbles, and were thus carried into the currents of the cirrus-cloud level of the atmosphere. The author has succeeded in obtaining artificial glass bubbles with blebs attached; but some accident seems to have prevented their appearance among his illustrations. He believes that some of the surface-glaze in australites results from fusion while falling through our atmosphere. F. Berwerth, it may be remembered (NATURE, vol. lxxxix., p. 513), used the absence of such signs of fusion in moldavites as an argument against the meteoric theory of their origin, and in this he received support from G. P. Merrill's work on australites. E. W. Skeats describes "three unusual forms of australites" from gravels in Western Victoria (Proc. R. Soc. Victoria, vol. xxvii., 1915, p. 362).

IN a review of "The Origin and Formation of the Diamond" (S. African Journ. Sci., vol. xi., 1915, p. 275), W. Johnson combats the theory that the South African diamonds were formed from carbon dissolved in molten kimberlite, and urges that pressure was the primary factor in their production, at a time when the igneous ground was buried in the crust far more deeply than it is at the present day.

THE Bulletin of the American Geographical Society for August, 1915 (vol. xlvii.), illustrates, in a paper by H. E. Gregory, of Yale, the huge buttes left in the Navajo country by erosion of red Permian sandstones. Wind is still the great enemy in this plateau

region, which lies between 4000 and 7000 ft. above the sea. The Colorado River is the only stream that maintains a strong flow throughout the year, and the meteorological records show great variations in rainfall from year to year, but indicate a brief rainy season in July and August. In the same number of the Bulletin, Sidney Powers, of the Hawaiian Volcano Observatory, provides some striking photographs of the lava-lake of Kilauea.

THE mineral and petrographic studies which form a special feature of the American Journal of Science are continued by W. E. Ford (vol. xl., p. 33), who investigates "the relations existing between the chemical, optical, and other physical properties of the members of the Garnet group," and in the following number by N. L. Bowen (*ibid.*, p. 161), who has experimentally investigated the crystallisation of simple types of basaltic and dioritic magmas. Mr. Bowen concludes that the more acid subalkaline igneous magmas are "derived from basic material, being, as it were, successive mother liquors from the crystallization of the basic magmas." Syenite may thus arise as an upper product of differentiation from a large slowly cooled mass of basaltic magma.

THE Canadian Department of Mines has issued recently three memoirs dealing with the coal resources of the Dominion; two are issued by the Geological Survey, namely, "Coal Fields of Manitoba, Saskatchewan, Alberta, and Eastern British Columbia," and "Coal Fields of British Columbia," both by D. B. Dowling, and one is issued by the Mines Branch, namely, "Products and By-Products of Coal," by Messrs. E. Stansfield and F. E. Carter. The two first-named deal more especially with the geology of the coal fields of western Canada, and will be welcomed by all interested in the geology of coal, more particularly because they deal with important coal deposits in relatively recent formations, Cretaceous and Tertiary. The third pamphlet will no doubt appeal to a wider public, its object being to present in a simple and accessible form the various economic applications of coal products, and, in the words of the authors, their "aim has been to give prominence to the commercial rather than to the scientific aspect of the subjects treated." Coke, gas, ammonia, tar, and the derivatives of coal-tar are briefly discussed in turn, and their economic and industrial importance is explained. Under the last head the question of the dye industry is touched upon, and the authors have quoted certain statements of Dr. Bernhard C. Hesse, of New York, which well deserve the widest possible publicity, showing, as they do, a remarkably sane and sound appreciation of the difficulties of the question. He points out that the coal-tar dye industry is not a unit, nor does it even consist of a number of independent units, but "is really a conglomerate of many separate parts acting and reacting upon each other, commercially and industrially"; his final conclusion being "that the whole of this industry cannot be successfully transplanted, and attempts to transplant part only have not resulted in any self-contained and independent industry anywhere."

THE *Monthly Meteorological Charts of the North Atlantic and Indian Oceans* for September, 1915, recently issued by the Meteorological Office, contain much which is of interest to the navigator. There is much else besides the precise detail as to the frequency of wind and current. An inset chart is given on the Atlantic issue showing the distribution of fog and mist over the ocean in September. It is shown that fog is seldom experienced on the steamer tracks in mid-Atlantic during September, and there is never as much as 20 per cent. in that month anywhere over the North Atlantic, as against 30 per cent. near Cape Race in August, and 40 per cent. in July. The Atlantic chart also contains on its reverse charts of the mean salinity and surface temperature of the North Atlantic and of the English Channel. The chart for the Indian Ocean gives graphically details of the ice in the southern hemisphere, also detailed information relative to the results of meteorological observations in the Persian Gulf and the Gulf of Oman.

ACCORDING to an article in the *Scientific American* for August 14, Dr. F. C. Brown, of the physics department of the State University of Iowa, has applied his discovery of the great sensitiveness to light of a selenium crystal as compared with the ordinary selenium film to the production of a "phonopticon" to enable blind persons to read printed matter. The instrument is a simplification and improvement of Dr. Fournier's "type-reading optophone." A box carrying a lamp, and provided with lenses, is moved along the line of print. By this means a short vertical bar of light moves along the line from left to right, and an image of the bar is cast on two or more selenium crystals in such a way that each crystal is covered by a fixed part of the line. Each crystal forms one side of a resistance bridge, which is balanced when the bar of light falls on white paper. Want of balance when the bar covers a portion of a printed letter is detected by a telephone in series with a rotating contact-maker. Each bridge has a contact-maker of a different period, and on listening to the joint effect of the telephones it has been found possible with not more than two telephones to recognise the sequence of sound for each letter of the alphabet.

WHILE the teaching of the calculus is now taken at an early stage in our curricula, the results do not appear to have been altogether satisfactory in America any more than here. We have recently received reprints of a discussion on "Practical Mathematics" opened by Prof. W. S. Franklin and his assistants before the Society for the Promotion of Engineering Education (Bulletin iv., 10, p. 5; Proceedings, xxii., p. 149), and we also have before us Prof. E. B. Wilson's reviews of recent text-books in the Bulletin of the American Mathematical Society for last June (xxi., 9). The failure of the students to profit by the course would appear to be due to the want of rigorous logical reasoning, to the failure to illustrate the subject by concrete physical and other illustrations, and to "the entire absence of suggestiveness in his mathematical studies and the inhibition of sense by the excessive formalities of ordinary

mathematics instruction." Prof. Franklin also raises certain objections to the syllabus definition of differentials, but we are sorry to see that he himself perpetuates the worst defects of our text-books by expanding series of powers of differentials. It is, of course, possible to expand $f(x+dx)-f(x)$ in powers of dx, and when the result is divided by dx the limit of the series does happen to be *equal* to the differential coefficient in most cases, but the differential coefficient cannot be *defined* as the limit of the series in question. It would be equally legitimate to expand $f(x)-f(x-dx)$ or $f(x+\frac{1}{2}dx)-f(x-\frac{1}{2}dx)$. The notion of a differential coefficient depends essentially on the assumption that the ratio of $f(x_2)-f(x_1)$ to x_2-x_1 tends to a unique limit when x_2 and x_1 both tend to the same finite limit x. Further, we think it would be much better to follow Newton's example by defining equality of differentials instead of trying to define the differentials themselves. The student who is taught always to *add dx* on to the end of x fails to grasp the very foundation of the calculus. The failing cases may be exemplified by "density" at a point *on* the surface separating two media.

WE have pleasure in directing attention to the little volume entitled "Manchester in 1915," which has been issued (in Manchester by the University Press, and in London by Messrs. Longmans and Co.) at one shilling net, it being the handbook for the forthcoming meeting of the British Association. While less pretentious than many previous association handbooks, it is a noteworthy production, and one which should be of great service to those attending the meeting; it will doubtless also appeal to many residents in and adjacent to Manchester, for it contains some very readable and informing articles on institutions of, and matters pertaining to, the city; thus, a brief historical sketch is contributed by Prof. J. Tait; Prof. Tout deals with the University, Dr. Tattersall with the museum, Mr. H. Guppy with the John Rylands Library, and Prof. Hickson with the Literary and Philosophical Society. Mr. Spurley Hey has two articles on, respectively, elementary education in Manchester, and secondary schools in Manchester, and Mr. J. H. Reynolds deals with the evening-school system of Manchester. In addition to the foregoing, the volume is finely illustrated by some fourteen plates—one in colour. Both text and illustrations are beautifully printed.

THE Institute of Chemistry proposes to issue a special edition (limited to 100 copies) of the history of the institute, 1877–1914, and orders for it can now be received. Any profit arising out of its sale will be devoted to the building fund.

MR. W. H. DINES informs us that a mistake occurs in his letter in NATURE of August 12 on "The Probable Error of the Amplitudes in a Fourier Series obtained from a Given Set of Observations." The passage in question should read:—"To obtain p we write $np/2=y_0 \sin 0+y_t \sin\frac{2\pi}{n}$. . . . etc., instead of $p=y_0 \sin 0$ . . . .

OUR ASTRONOMICAL COLUMN.

ABSOLUTE STELLAR MOTIONS.—*Meddelande* No. 65, from the Lunds Astronomical Observatory, gives an account of an important statistical study of the distribution of the absolute motions of a number of parallax stars which has been made by Mr. K. W. Gyllenberg. After excluding parallaxes smaller than 0·015″, there remain 160 stars for which absolute velocities can be determined. The components were calculated for an axis "Z" pointed to the galactic pole, an "H" axis in the plane of the Milky Way, whilst the third "Ξ" was directed towards the vertex found for 1470 stars with known radial velocities. The numerical work was curtailed by using Prof. Charlier's plan of dividing the sky into forty-eight compartments, and using the co-ordinates of the centres for the contained stars. Prof. Charlier's units Siriometer (1 Sm = 10^6 dist. earth-sun) and Stellar-year (1 St. = 10^6 years) have been used (1 Sm/st. = 4·7375 km./sec.). After arranging the material according to type of spectrum, five star types, K1 (Arct.) to A2p (Cyg.), were excluded as having excessive velocities. The greatest mean velocities were found in the plane of the galaxy, the "Z" components giving the smallest mean value. The absolute velocities tend to increase as the parallax diminishes, but the increase is more rapid for the small parallaxes, probably due to the greater insecurity of these measures. Hence in the final stage of the work stars having parallaxes less than 0·025″ were excluded. It is concluded that the distribution of the absolute velocities for the remaining 144 stars is approximately represented by an ellipsoid of revolution flattened in the plane of the Milky Way, and, unlike the proper motions or radial velocities, the absolute motions show no principal vertex.

THE SOLAR ECLIPSE OF APRIL 17, 1912.—We have received copies of two papers by Señor P. Carrasco, of the Madrid Observatory, reprinted from the Annals of the Physical and Chemical Society of Spain, dealing with the above eclipse. One of these papers (*Ann.*, vol. xii., pp. 482–99, 1914) gives a general description of the eclipse and of the work done at Cacabelos (Leon) by Señor Carrasco, who had charge of the spectroscopic work in the eclipse party under Señor Cos, organised by the Institute of Geography and Statistics. The central line of totality, it is estimated, passed about 2700 metres south-east from the position occupied at Cacabelos (3° 1′ 39″ W., Madrid, 42° 35′ 53″ N.). The observers saw something rather less than totality, but more than a mere partial phase. In the second paper (*Ann.*, vol. xiii., pp. 181–238, 1915) the spectroscopic observations are discussed. The prismatic camera employed had "two (?) quartz prisms of 60° angle, 48 mm. in height, with an objective of 50 mm. aperture and 630 mm. f.l." *Five* exposures were made in *ten* seconds on one plate (Agfa), 13×18 cm. Three of these spectra have been measured and reduced (Cornu-Hartmann formula, Rowland's solar wave-lengths, and Kayser's Hauplinien). The results are given in a table of some 2000 chromospheric lines between λλ3334 and 5897. The ultraviolet region to λ3900 has been mapped. The conclusions reached are in good accord with those now generally accepted; thus, although Fraunhofer lines are common to both spectra, yet the intensities are notably distinct, the larger chromospheric arcs agreeing better with the spark than the arc spectrum, and the principal lines of the high chromosphere correspond with the enhanced lines of Sir Norman Lockyer.

ANOMALOUS DISPERSION IN THE SUN.—Last year Prof. Julius, by a development of the theory of anomalous dispersion, concluded that there must be

a mutual influence of closely neighbouring Fraunhofer lines. Early in the present year, however, Dr. St. John, discussing the same data employed by Julius, obtained a negative result. The matter is now carried a stage further in the June number of the *Astrophysical Journal* by Mr. Sebastian Albrecht. In this valuable paper a comparison is made of Rowland's solar wave-lengths of iron lines and the laboratory wave-lengths of the same lines to determine whether systematic differences are shown by lines having close companion and isolated lines. The paper hinges on a discussion of laboratory wave-lengths. All iron lines which have been classified according to pressure effect were examined, and consequently a chief feature of the paper is a complete list of Rowland's solar wave-lengths and corresponding international wave-lengths of these lines. International secondary standards were, of course, adopted without modification; for other lines a comparison was made between the sea-level determinations of Burns and the Pasadena-Mount Wilson values of St. John and Ware. A systematic difference so disclosed was ascribed to differences in the *internal* pressure of the arcs employed. The corrections to reduce the I. Å. values to a pressure of 0·5 atm. (the pressure of the solar reversing layer) were applied, and differences, Row., λ I. Å. 0·5 atm., as well as Row. λ I. Å. 1 atm., were tabulated. Systematic differences between Rowland and the international system were eliminated subsequently by means of a curve. The following table concisely exhibits the principal results obtained:—

Means—Displacement according to Separation of Lines.

Lines with	Separation		
	0·0 to 0·2 A	0·2 to 0·4	0·4 and greater
Companion towards red ...	+0·0103 ...	+0·0065 ...	+0·0036
,, ,, blue ...	−0·0073 ...	−0·0024 ..	−0·0010

A REMARKABLE GROUP OF SOLAR SPOTS.—The solar surface has recently displayed considerable activity, and possessors of telescopes have been much interested in the number and variety of spot groups almost continually visible. One large group which appeared during three, and possibly four, rotations forms the subject of an article by M. Camille Flammarion in the July number of *L'Astronomie.* An account is given of the solar activity during the spring months, and associated terrestrial, magnetical, and electrical disturbances.

A CATALOGUE OF STAR CLUSTERS.—The star clusters shown on the Franklin-Adams chart plates have been catalogued by Mr. P. J. Melotte (Mem. Roy. Ast. Soc., vol lx., part 5). The scale of the plates has been found excellently well adapted for the purpose, the open clusters not being dispersed by excessive magnification, whilst the scale is sufficient to show the features of globular clusters down to 3′ diameter. The catalogue contains 245 entries, and in addition to the usual co-ordinates (1900), galactic longitudes and latitudes of the various objects are also tabulated. The clusters have been classified according to degree of condensation in the following scheme of four classes:—(1) Globular clusters, condensed at centre; (2) loose clusters having regular well-defined outline; (3) loose clusters of irregular outline; (4) coarse clusters. By plotting with reference to Milky Way and classification it was found that practically all lie within ±30° of the galactic plane, whilst the globular clusters also tend to concentrate in a particular longitude rather more than half lying within 30° of galactic longitude 325°.

INDIGO IN INDIA.

THAT the production of natural indigo in India is at present receiving the scientific attention which is its due must be welcome to many. The evidence that this is the case will be found in a Report on the Improvement of Indigo in Bihar, with Notes on Drainage and on Green-Manuring, by Mr. A. Howard, Imperial Economic Botanist at Pusa, and Mrs. Howard, published in 1914 by the Bihar Planters' Association, and republished this year, with a second report by the same authors, on behalf of the Pusa Agricultural Research Institute.

The old belief that the source of the natural indigo of commerce is the species of Indigofera distinguished as *I. tinctoria*, though accepted by many chemists and some botanists in Europe down to the close of last century, was singularly incorrect. That the species in question does yield indigo is true; that at one time it was a main source of the dye is possible. It is, however, improbable that any appreciable amount of commercial indigo has been derived from *I. tinctoria* during the past hundred years.

When the intercourse between Europe and India which followed the discovery of the Cape route began, there were two main centres of indigo production and export. One of these was Surat, in Western India, where the plant employed was a form of Egyptian indigo, *I. articulata*, still the staple indigo plant in Eritrea, and still to be met with as a native crop in parts of Scinde, Rajputana, and the Deccan. The other was in Southern India, especially in Coromandel, and in Ceylon. The plant grown in this area differed much from Egyptian indigo. We may speak of it as Indian indigo, though with some reserve, because a plant from which indigo is obtained in Northern Nigeria cannot be distinguished from the Coromandel one, while a form closely related to it, which is wild in Nubia and the Eastern Sudan, has by some writers been believed to belong to this species. It is not inconceivable that the cultivated plant of Southern India may, like that of Scinde, have originally found its way east from Africa, and it is possible to imagine that on its way west from its original Nubian home to Nigeria, cultivation may have induced in it the same modifications as have taken place on its way east to Madras. The point which immediately interests us, however, is the fact that the name *I. tinctoria*, as originally employed, connotes the cultivated indigo of Coromandel.

European needs induced an extension of indigo cultivation. That of the Egyptian plant spread east from Scinde to the Panjab, and thence along the Gangetic Plain to the province of Bihar, in later times so closely associated with the manufacture of indigo. The cultivation of the Indian indigo spread to Malaya in the east, to the coasts of Madagascar, Zanzibar, and Socotra in the west; somehow, this indigo has even reached Northern Queensland. But neither plant extended to Bengal, or to Indo-China and China beyond Bengal. In Malaya the cultivation of Indian indigo went on along with that of a third plant, *I. sumatrana*, which we may speak of as Malayan indigo; this plant has found its way eastward to Formosa and, during the supremacy of the Dutch in Western India, was brought from Sumatra to Malabar, where it displaced both Indian indigo and yet another dye-yielding Indigofera. This fourth plant, *I. longeracemosa*, hardly deserves a commercial name, and only calls for mention because it has found its way to the Mascarenes and Zanzibar, and is preferred there to the other dye-yielding species.

This is not the place to discuss the policy which, early in the seventeenth century, laid an embargo on

Indian indigo, or to explain how, when that embargo was withdrawn, American indigo came to replace the Indian dye in European markets. What does interest us is that this American indigo was mainly the product of a fifth plant, *I. suffruticosa*, Brazilian indigo, grown both in South America and in the West Indies, and of a sixth, *I. truxillensis*, West Indian indigo, grown both in the West Indies, where it was the favourite indigo, and in Central America. The cultivation of Brazilian indigo spread more widely than that of any other kind; it found its way all over Polynesia, and became established in the Philippines. From Manila it extended throughout Malaya, where the Brazilian, Malayan, and Indian indigos were grown side by side, and reached Formosa, where it still competes with Malayan indigo. Similarly, this Brazilian indigo has found its way into all parts of Indo-China and into south-eastern China; in Indo-China and China this American plant is the only dye-yielding Indigofera yet known. In the opposite direction, the Brazilian indigo spread to the African coast, on the western side displacing an indigo already in cultivation, on the eastern finding a place alongside various Asiatic forms. It is interesting to note that by neither route did Brazilian indigo ever reach India.

The area occupied by the Indigofera which yielded the indigo known to the ancients extended in classical times, as it does still, from Egypt and Nubia to North-West India. Immediately to the south of the region in which the Egyptian indigo grows, from the highlands of Abyssinia as far as Zululand, occurs a seventh plant, *I. arrecta*, East African indigo, the cultivation of which has spread east to the central highlands of Madagascar and west to the coast of Guinea. Along that coast, however, from Angola to Senegal, this indigo at a later date was largely supplanted by Brazilian indigo.

The circumstances which, towards the end of the eighteenth century, led to a revival of the Indian indigo trade lie outside the scope of this article. This successful enterprise had its principal seat in the three Lower Provinces of Hindustan—Bengal, Bihar, and Orissa. The plant at first grown was a form of the Egyptian indigo; this was still cultivated in Bihar in 1812. In Bengal and Orissa, where indigo had not before been grown, this Egyptian indigo, better suited to a somewhat drier climate, was soon replaced by Malayan indigo. From Bengal, where the cultivation of indigo ultimately died out, the Malayan plant extended into Bihar, displacing the Egyptian. From Bihar this plant spread westward throughout Upper India and across the Panjab to the district around Multan, which eventually became a favourite source of the seed for the Bihar crop. From Orissa, where its cultivation likewise came to an end, the Malayan plant invaded the area in South India where *I. tinctoria* was once the staple source of the dye, displacing that Indian indigo so effectually that now *I. tinctoria* is only found in the Laccadive and the Maldive Islands, and in some parts of Ceylon, where the share taken in the eighteenth-century effort to promote the cultivation of indigo was insignificant. If, however, this Malayan plant did not reach Ceylon it was taken to Senegambia, as the "Indigotier de Bengal," to replace Brazilian indigo, and was similarly taken to the West Indies to replace *I. truxillensis*.

From Senegambia the Malayan indigo has found its way as far as Northern Nigeria, where it now grows in company with a form which cannot be distinguished from the indigo once widely cultivated in Southern India. Allusion has already been made to the possibility that the latter form may have originated in Africa, but the more probable, if more prosaic, explanation of its presence in Nigeria is that when seed of the Malayan indigo was taken to West Africa from Chandernagore in Bengal, a supply of South Indian seed was also taken from Pondicherry in Coromandel. But while we know that the first transaction took place, we can as yet only surmise the second.

In the West Indies the cultivation of Malayan indigo did not take root as it did in India and in West Africa. The effects of the competition by India had made themselves felt before the Malayan plant reached the islands. Where indigo-growing was not abandoned in favour of sugar and cotton, the West Indian plant, which was at least as valuable as the Brazilian, even if it was inferior to the Malayan one, had already been displaced by an eighth species, *I. guatimalensis*, Central American indigo.

Although Ceylon took no part in the revival of the eastern indigo trade, the Dutch East Indies did. At first, as we have seen, the Indian, the Malayan, and the Brazilian indigos were all grown; later, however, the Malayan plant, just as in India, displaced all other kinds. But in Java a further step, never adopted in India, came to be taken; Central American indigo, *I. guatimalensis*, was introduced, and displaced the Malayan plant, *I. sumatrana*. Later still, yet another displacement occurred; about the middle of the nineteenth century the East African indigo, *I. arrecta*, found its way from Zululand, through Natal, to Java; by the time that the competition of synthetic indigo had begun to be serious, this African plant was practically the only indigo cultivated in Java.

Displacements of economic species depend on economic factors. In the case of indigo, the explanation has been either that the newly adopted species was found to yield more leaf from a given cultivated area or more dye from a given weight of harvested leaf; in the case of East African indigo, it would appear that Java experience has found these two advantages combined in the same species. It was not until 1898, as Mr. and Mrs. Howard explain in their First Report, that it was realised in Bihar, where the competition of synthetic indigo had at last aroused concern, that in Java not merely one, but two, displacements of the plant which was the basis of the industry had taken place since India and Malaya re-embarked upon it in the late eighteenth century. Some Bihar planters then introduced the African plant from Java; a few seasons later direct importation of seed of *I. arrecta* from Africa took place.

The cultivation of East African indigo, which is in India termed Java indigo, though it is not a native of Java, and is in Java termed Natal indigo, though it does not grow in Natal, gradually spread until 1909–10, and bade fair to displace Malayan indigo in Bihar. An abnormal season, followed by another of the same type, then led to a check. Indigo growers became so alarmed at what they mistook for an outbreak of disease that by 1913 the area under East African indigo had fallen from 70,000 to 15,000 bighas. Had their memory enabled them to recall the experience, duly recorded at the time, with regard to the cultivation of *I. arrecta* near Calcutta, under equally abnormal conditions, ten years earlier, a suspicion might have been aroused that what was needed was the correction of some defect in the cultivation and the bestowal of some attention on the seasonal peculiarities of the East African plant. The investigation of the imaginary disease was placed in the competent hands of Mr. Parnell at Sirsiah, who in 1913 was unable to report the discovery of any pathogenic organism. Mr. Howard, who then had

an opportunity of discussing the matter, came to the conclusion that the symptoms which had alarmed growers were attributable to bad cultivation and water-logging of the soil.

Since 1913 the experimental work commenced by Mr. Parnell at the now abandoned Indigo Research Station at Sirsiah has been continued at Pusa by Mr. and Mrs. Howard, whose work, as detailed in their First Report for 1914, has satisfactorily disposed of the unfounded dread that East African indigo had in India fallen a victim to some mysterious malady. In this and in their Second Report for 1915, the authors have further shown planters how a recurrence of the difficulties experienced since 1910 may be avoided, and have taught them that a treatment with which they were familiar as regards Malayan indigo calls for modification when the East African plant is in question. But they have done more than this; in the words of a writer in the Allahabad *Pioneer*, one result of the work of Mr. and Mrs. Howard is that "one bugbear of the Java indigo planter—the impossibility of obtaining good seed—is on the highway to being removed." The beneficial effect of their work, however, does not end here; in their Second Report they point out with a directness to which the planting community have not been accustomed, that the future of their industry in Bihar will depend on their ability to increase the yield of indigo from the plant. If the advice given in the Report for 1915 be followed, there may still be some hope as to the future in store for the industry, the object of which is the production of natural indigo. It is true, as the sympathetic writer in the *Pioneer* remarks, that many improvements will be necessary if this industry is to re-establish itself. The friends of the Bihar planter—he has, and he deserves to have, many—for years past have urged this necessity upon him, and it is but fair to say that he has taken the advice to heart. But his most genuine well-wishers have not hesitated to remind him that, so far, he has failed in one important particular—he has not recognised, as he might, his own limitations. His "associations" and his "syndicates" serve many legitimate and useful purposes. But the direction of research in connection with indigo has clearly not been their *métier*, and if the two Reports by Mr. and Mrs. Howard enable this truth to be realised they will have done good which should outweigh even the immediate material benefit which they confer on a singularly deserving community.

For his attitude towards the plant and its product the indigo-planter is not wholly to blame. The stranger can teach him little with regard to the cultivation of the particular plant with which he is familiar. To his colleague the chemist there is, after all, but one indigo. When the indigo-planter knows, as the botanist tells him, that among the forty kinds of tobacco, the twenty kinds of wheat which surround his dwelling, he has to do with but one species of Nicotiana and one of Triticum; when he observes that it is easy to find two tobaccos and two wheats differing in outward characters more markedly than any two indigo plants of his acquaintance do; it is scarcely surprising if he be influenced by a subconscious belief that, after all, the indigo plants may be only forms of one Indigofera, and that the treatment suitable for one may well serve for another. Nor is it quite certain that the botanist, whose task it is to keep the planter right, is always free from a similar unwitting prejudgment. The tangled synonymy with which the history of these tinctorial species of Indigofera is loaded, and the instinctive tendency to suggest that each new one may be a modified form of *I. tinctoria*, point to this possibility. That this is not the case those who have grown the different tinctorial species together and have compared them at various stages of growth can testify; those who have made a critical herbarium study of the material available express the same judgment. Even in such as have not enjoyed these opportunities, a consideration of the history of these tinctorial indigos from a botanical point of view may perhaps induce a reservation of judgment. The hope of effecting this, and the desire to assist the planter to realise that the displacement of one indigo plant by another is nothing new and has never been unreasoned, may serve as an excuse for the *résumé* of these displacements here given.

RESEARCHES ON PHAGOCYTOSIS.

I.—*Introduction.*

ALTHOUGH the number of the white blood-corpuscles, compared with that of the red, is small (1 leucocyte to ±350 red blood-corpuscles), the absolute number of them is rather considerable; for in the five litres of blood, which is the usual quantity for a man of normal size, there are 80,000,000,000 leucocytes.

A part of these leucocytes has, owing to their plasticity, the property of enveloping and in this way taking up all sorts of particles, as, for instance, coal-dust, grains, and also bacteria. It is because of this property that these cells, which have a diameter not larger than about 0·008 of a millimetre, have engaged our attention, especially since Metchnikoff has established that bacteria englobed by these cells are killed in them, and are thus made innocuous to our body. For this reason he has called them phagocytes (eating cells), and their process of eating *phagocytosis*.

The life of these cells deserves our interest; but until now it has not been, as such, the object of a systematic investigation, a fact Metchnikoff himself regretted in a paper he read some years ago to the students of the University of Amsterdam on "Réactions Phagocytaires." [1]

Now I must confess that the importance of the phagocytes for the defence of our body against bacteria has not been the first and principal reason of my investigations with these cells: the principal reason was their being an excellent object for researches of a general biological nature.

I think a physiologist in the first place must practise science for its own sake, not asking whether his work may be of immediate practical use, but should he, however, accidentally stumble upon an idea which may be directly used for the bodily welfare of mankind, this should not prevent him from giving his attention to this; in fact, it is his duty to do so.

The phagocytes are a suitable object for studying life phenomena. In the first place, they are not such complicated organs as the muscles, heart, brain, etc.; they are simple cells, easily isolated. Secondly, it is possible to follow quantitatively the effect on their life of slight alterations of their natural medium.

It is obvious that the phenomena produced by the agency of solutions not dangerous to life are, in fact, nothing else but the effects of reactions which finally will help us to penetrate further into the physical and chemical structure of the living cell.

The investigations on the life of phagocytes, which during the last years have occupied myself and my collaborators, are a continuation of researches begun several years ago (1883) with the object of ascertaining the influence of salt solutions of various concentra-

[1] Nous ne sommes qu'au début. Lorsqu'on connaîtra mieux *la physiologie des phagocytes*, on cherchera des méthodes pour augmenter l'activité de ces éléments dans la lutte contre les microbes et on cherchera d'autres pour préserver contre l'attaque des phagocytes les cellules nobles de notre corps.

tions upon the red blood-corpuscles, and of the significance of these results with regard to the functions of the body. These researches on the red blood-corpuscles, which introduced physical chemistry into medical science, were confined to the study of their chemical and volumetrical alterations.

But the influence of the salt solutions on the very life of the cells could not well be tested on those particular objects, although systematically investigated. We have felt this from the beginning, and repeatedly asked ourselves whether the solutions producing the chemical and volumetric changes of the red blood-corpuscles had or had not seriously damaged these cells, and thus, whether it was possible to apply the conclusions arrived at to problems regarding life itself. Therefore, wherever it was possible, we examined whether the phagocytes, being submitted to the same agencies, kept their phagocytarian power. This was always the case. This conclusion enhances the value of our researches on the red corpuscles, the more so because the chemical and volumetric alterations of the white cells corresponded with those of the red ones. But a systematic study of the life of the leucocytes had not, previous to our researches, been undertaken, and this is rather surprising.

II.—*Method of Investigation.*

Our method has been very simple. White corpuscles (leucocytes) from the blood of a horse are transferred to various media mixed with very small particles of carbon. After having stood some thirty minutes in an incubator at body temperature a great many of the cells have eaten up carbon. Microscopical preparations are made, and it is ascertained what percentage of the leucocytes has taken up carbon. *This percentage is the measure for the degree of phagocytosis and gives the value of the influence of the various agents used on that function of life.*

Suppose in examining 600 leucocytes lying in their natural medium (blood serum) I find that 300 of them have taken up carbon, the percentage of phagocytosis can then be expressed by $300/600 \times 100 = 50$ per cent. In order to examine, for instance, the influence of small amounts of acid, I add this substance to the serum and repeat the same experiment under the same conditions. I now find that of the 540 examined leucocytes only 200 have taken up carbon. The phagocytosis is now expressed by $200/540 \times 100 = 37$ per cent. Thus the addition of acid to the serum has lowered phagocytosis.

This calculation is based on the principle that the phagocytic power of the individual phagocytes present in a suspension is unequal, a fact which cannot be wondered at when we take into consideration that they are of different age. The more detrimental the action of the agent, the smaller should be the number of phagocytes which take up carbon in the same space of time.

Our selection of an indifferent substance such as carbon instead of bacteria, was based upon the fact that we otherwise feared our work would become too complicated. We here refer to the fact established by Sir Almroth Wright and his school that most kinds of bacteria, before they can be taken up by the phagocytes, must undergo a certain amount of sensitisation. Hence it follows that the intensity of phagocytosis will not only be influenced by the agent, as such, but also by the degree of "sensitisation" the particles have undergone. Another fact which had to be borne in mind was that the bacteria sometimes secrete poisons, which have an injurious effect on the phagocytosis. Even dead bacteria contain poisons.

The selection of carbon as an indifferent substance instead of the usual grains of carmine was based upon the greater facility and accuracy with which the taking up of carbon can be ascertained. I shall not here give a detailed description of the method of obtaining the leucocytes, or of preparing the carbon, or of the method of determining the percentage of cells which have eaten carbon. I prefer to give some of the more striking results.

III.—RESULTS.

(1) *The Influence of Small Amounts of Calcium.*

In examining systematically the influence of the addition of small amounts of various salts (ions) to the blood-serum, it was found that very small quantities of calcium increased the phagocytosis to a considerable extent. An addition, for instance, of 0·005 per cent. of chloride of calcium ($CaCl_2$) to the natural medium (serum) caused an increase of about 22 per cent. in the phagocytic power. This favourable effect becomes even more strongly manifest when, instead of being added to the suspension of phagocytes in serum, the calcium is added to a suspension of phagocytes in a solution of chloride of sodium (common salt), in which phagocytosis occurs almost to the same extent as in serum.

These investigations have been continued in two directions. In the first place, we asked ourselves whether the influence of calcium would also manifest itself in the living body. All experiments had hitherto been made outside the body. It will be remembered that on placing under the skin (for instance, on the inside of the thigh of a rabbit) small capillary tubes, closed at one end and filled with an extract of bacteria in a solution of chloride of sodium, phagocytes enter these tubes. This phenomenon is called Chemotaxis, and is based upon the creeping movement of the phagocytes towards the excretions and secretions produced by the bacteria.

After a certain lapse of time, the open part of the capillary tube is filled with a white column consisting of phagocytes. If, in fact, calcium promotes the activity of the phagocytes, not only in the phagocytic process described above, but also in the living body, we argued it might be expected that by calcium that mobility of the cells, which here finds its expression in chemotaxis, would be accelerated. Therefore we determined the length of the white column formed in the capillary tube with animals, either treated with calcium or not so treated.

We expected to find that in rabbits treated with calcium the white column would after the same space of time be longer than in animals not having been treated with calcium. We have used two methods, which gave the same result. I will mention one only. It consisted in injecting into the rectum of two series of animals a solution of chloride of sodium mixed for one series with calcium, and for the other without calcium, and then examining the length of the column of phagocytes penetrating into the capillary tubes.

The difference between the two series was considerable. The calcium-rabbits showed the greatest degree of chemotaxis, although the amount of chloride of calcium used was very small, viz., 0·06 gr., a quantity corresponding with that given to man in mineral waters rich in calcium. Let us add that a natural mineral water used in our experiments gave the same results as the chloride of calcium solution.

What can be said of the mechanism of this effect? The calcium, on being absorbed by the mucous membrane of the rectum, enters the blood-circulation and by this is carried into the lymph of the tissue-spaces; where the glass capillary tubes are placed. The phagocytes which are there will soon undergo the stimulating influence of the calcium thus introduced, *i.e.* their mobility will be increased and chemotaxis will be promoted.

Even without measuring the length of the phagocyte columns, we may convince ourself that our conclusion as to calcium promoting the activity of the phagocytes is the correct one. On opening the skin wound, it is immediately seen that in the mineral-water-rabbits a much thicker mass of phagocytes is gathered round the tubes than in the pure sodium-chloride-rabbits. The same thing we observed invariably in all experiments where NaCl-solution containing calcium-chloride was injected.

Taking for granted that phagocytosis is playing a part in defence against microbes, we may infer from the above that an enrichment of our blood, and through this also of the lymph spaces, with small amounts of calcium must have a favourable effect on local and other infections.

There are many experiences supporting this view. I will mention only two examples. In the first place, Sir Lauder Brunton has used with great success chloride of calcium in pneumonia. Other clinicians have also met with success along the same lines; for instance, Crombie, who some years earlier, in the hospital of Calcutta, saw the mortality decrease from 38·6 to 5 per cent. He is inclined to attribute the influence of calcium to an action on the poison excreted by the pneumonia bacteria. But for this there is no evidence. Sir Lauder Brunton has recommended calcium for getting amelioration of the heart-action. In recovery from pneumonia the amelioration of the heart-action is of the greatest importance. So it was quite rational that the famous clinician and pharmacologist advised calcium for this purpose: in the first place, because it was pointed out by the work of Sydney Ringer that calcium is absolutely necessary for the heart-function, and, on the other hand, Langendorff and Hueck had found that by the injection of calcium into the circulation of a cat the action of the heart was considerably strengthened.

Sometimes it happens that during surgical operations the heart-beat is stopped by the inhalation of chloroform. The idea occurred to me that in this case calcium might be able to be of good service. Therefore I tried to improve the heart-action by intravenous injection of calcium in animals, which had been given purposely too much of the anæsthetic. I had no success; so I began to doubt whether calcium was really capable of stimulating even the normal heart. In a number of experiments I made I found that injection of calcium had no effect on the heart-beat of a normal animal. Studying the original article of Langendorff with renewed attention, I saw that he had performed only one experiment. His great reputation had given his assertion general acceptance, and so it had become a fact in the literature. Obviously the amount of calcium in the normal blood-serum provides already just the optimum quantity for the heart function.

Thus this favourable effect of calcium in pneumonia not being explained by the influence of calcium on the heart, we had to look for another reason. It was therefore most natural to remember the stimulating action of the calcium on phagocytes, which in pneumonia play such a preponderant part.

My second argument for the probability that calcium is of importance in infectious diseases is this: labourers in lime-kilns do not get tuberculosis; in Holland these workmen cover any wound they receive with lime.

The significance of calcium has for some time past been occupying the special attention of biologists and pathologists in an increasing degree, and I shall speak of it further now, and of the cause of the promoting of the activity of the phagocytes in phagocytosis and chemotaxis by calcium, only to make one remark. We might be inclined to attribute the increase of the plasticity to a modification in the aggregation of the colloid-protoplasm-particle as a consequence of the electric charge caused by the entering of a number of bi-valent calcium ions into the cells. This explanation, however, can scarcely be the correct one here; for experiment shows that other bi-valent kations, namely, barium, strontium, and magnesium, do not augment the amœboid motion, *i.e.* of phagocytosis and chemotaxis. It must be assumed, then, that the action of calcium in this case is based upon a hitherto unknown specific biochemical property of this metal.

(2) *Influence of Iodoform on Phagocytosis.*

Everyone knows that for the last thirty years iodoform has been successfully applied in the treatment of wounds and chronic inflammations. At first it was thought that this favourable effect was based upon an antiseptic action, but the idea was relinquished when it was found that lower organisms develop fully in a medium containing iodoform. Then other hypotheses were suggested, which need not be dwelt on. They are founded mainly on iodine being split off. None of these have proved satisfactory suggestions. For reasons unnecessary to state here, we have raised the question whether the favourable effect of iodoform on local infections may be due to the stimulating effect of this substance on phagocytosis. To answer this question iodoform solutions of different concentrations in a common salt solution of 0·9 per cent. were prepared and mixed with a thick suspension of white blood-corpuscles. After having added carbon particles, the mixtures were left to themselves for half an hour in an incubator at 37° C., and then cooled down. Finally, microscopic preparations were made and examined to determine what percentage of the total number of white blood-corpuscles had taken up carbon particles. The following table contains the results of the experiment.

Concentration of Iodoform Solutions in which the Effect on Phagocytosis is still perceptible.

Fluids	Percentage of leucocytes having taken up carbon	Per cent.
NaCl 0·9 per cent. (common salt solution of 0·9 per cent.)	$\frac{171}{388} \times 100 = 44$ $\frac{151}{345} \times 100 = 43·7$	43·8
1 iodoform to 100,000 NaCl 0·9 per cent.	$\frac{221}{374} \times 100 = 58·6$ $\frac{226}{377} \times 100 = 59·9$	58·2
1 ,, 500,000 ,, ,,	$\frac{228}{371} \times 100 = 61·4$	61·4
1 ,, 2,000,000 ,, ,,	$\frac{208}{398} \times 100 = 52·2$ $\frac{231}{445} \times 100 = 51·9$	52
1 ,, 5,000,000 ,, ,,	$\frac{292}{021} \times 100 = 46·9$ $\frac{176}{372} \times 100 = 47·3$	47

This table shows that, in the pure salt solution, of the 388 examined leucocytes 171 have taken up carbon, *i.e.* 44 per cent. In a parallel experiment the percentage was 43·7 per cent. Thus the average was 43·8 per cent. In the salt solution containing iodoform in a proportion 1 gr. iodoform to 100·000 gr. NaCl solution, the percentage in two parallel experiments was 58·6 and 59·9; average 58·2 per cent. Evidently the iodoform promoted phagocytosis.

These and other parallel experiments illustrate also the exactitude of the method. As a matter of course, control experiments have been made in all cases.

Further, it appears that a weaker solution of iodoform (1 : 500,000) yields a still higher phagocytosis (61·4 per cent.). The explanation of this phenomenon will afterwards be given. It is seen that in still weaker concentrations the phagocytosis is diminished, but even in a solution of 1 iodoform to 5,000,000 salt solution, the promoting effect of iodoform is still perceptible, for it is 47·1 per cent., whereas in a pure NaCl solution it was $\frac{1}{2}(44+43\cdot7)=43\cdot9$ per cent.

The favouring effect of iodoform is still more evident when the leucocytes are placed for several hours in a pure NaCl solution. Then the phagocytosis falls to a considerable extent. Sometimes the phagocytes are quite paralysed. The addition of iodoform in a concentration 1 : 5,000,000 then raises the phagocytic power by 30 per cent. or more. Thus there is no doubt that iodoform is able to promote phagocytosis. *Is it the iodine or the iodoform as such?* We have found that iodine is noxious in a high degree. We must conclude, therefore, that iodoform as such causes the increase of the phagocytic power.

The question now suggests itself: How can the favourable effect of iodoform be explained? It may be accepted from numerous investigations that the outer layer of the cells consists of a fatty substance, a so-called lipoid membrane. Now iodoform is soluble in fat, and it is quite obvious that such a membrane will grow more soft and more flexible after having absorbed iodoform, and that consequently the plasticity and mobility will be facilitated.

If this interpretation be correct, then other substances soluble in fat, such as chloroform, chloral, alcohol, benzine, camphor, fatty acids (propionic, butyric acids) should affect phagocytosis in a similar way. This is found to be invariably the case.

(3) *Effect of Chloroform, Alcohol, Camphor, Benzine, and other Substances Soluble in Fat on Phagocytosis.*

I shall not give an account of all our experiments made in this direction. I only give as an example an experiment with chloroform, from which one can at once get an idea as to the exactitude of the method. It was soon found that dilutions 1 : 2000, 1 : 6000, and also 1 : 10,000 paralysed the phagocytes. The following table contains some experiments with weaker solutions :—

Effect of Chloroform on Phagocytosis.

Fluids	Percentage of leucocytes having taken up carbon	Per cent.
NaCl 0·9 per cent.	$\frac{174}{428}\times 100=40\cdot6$	40·9
	$\frac{238}{562}\times 100=41.2$	
Chloroform 1 : 20,000	$\frac{244}{480}\times 100=50\cdot8$	50·3
	$\frac{225}{451}\times 100=49\cdot8$	
,, 1 : 100,000...	$\frac{254}{519}\times 100=60\cdot6$	60·3
	$\frac{382}{455}\times 100=60\cdot1$	
,, 1 : 500,000...	$\frac{332}{582}\times 100=57$	58
	$\frac{219}{370}\times 100=59\cdot1$	
,, 1 : 5,000,000	$\frac{379}{868}\times 100=43\cdot6$	44·3
	$\frac{298}{661}\times 100=45$	

From this table it appears that chloroform 1 : 20,000 raises the phagocytosis power from 40·9 per cent. to 50·3 per cent.; further, that phagocytosis is considerably increased by chloroform 1 : 100,000, in which case it rises to 60·5 per cent. Evidently in the chloroform-solution 1 : 20,000 the paralysing influence also makes itself felt. In a dilution of 1 : 500,000 the favourable effect remains to about the same extent as in 1 : 100,000, and finally in a solution of 1 chloroform to 5,000,000 NaCl-solution, this favourable effect is still visible, though slight.

Similar results were obtained with benzine, camphor, turpentine, alcohol, chloral, fatty acids (propionic and butyric), and also Peruvian balsam. These all, without exception, promoted phagocytosis. Hence our hypothesis for explaining the effect of iodoform was fully confirmed. Another strong support to our hypothesis was obtained by comparing the concentrations of the named substances which were able to increase phagocytosis. It appeared that the relation between these concentrations corresponded with that existing between the solubility of these substances in fat.

Further, all the substances applied in very small doses showed a stimulating effect, but paralysed when given in greater quantities. This can be explained by distinguishing two factors. First, slight quantities of the substance by dissolving in the outer layer of the cell weaken it and increase the plasticity and mobility. Then, greater quantities having entered the cell, a second factor, the paralysing effect on the protoplasm, comes into play. As the amount of chloroform is increased, the paralysing effect gets the precedence and no carbon at all is taken up.

4. *Other Phenomena seen in the Light of the Foregoing Facts.*

The effect of fat-dissolving substances on phagocytes throws a new light on several facts which were until now for the most part entirely unexplained. In the first place, we may refer to the power of turpentine to cause local exudations, and the favourable effect of a subcutaneous injection of the same substance in the treatment of pneumonia with horses and of mastitis with cows, which for some time has been practised with great success in France, Denmark, and Holland. Experiments made by us in this direction have shown that there is much reason to attribute this effect to very small quantities of turpentine dissolving in the lymph of tissue-spaces and afterwards entering the blood circulation and promoting the phagocytic power of the phagocytes in lung and udder.

In the same way we can explain the marked effect of camphor-treatment in inflammatory processes of the uterus and its adnexa, an effect not understood hitherto. Then there is the great effect of covering infected wounds with "balsam of Peru," the therapeutic value of inhalation of turpentine-vapour in tuberculous and other infectious processes in the respiratory organs.

In all these cases a stimulating action on the phagocytes, and probably also on other cells (granulation-cells), which play a part in the healing process, may come into play. Yet more becomes clear to us from the above researches.

It is well known that various narcotics applied in smaller doses have a stimulating effect and paralyse in greater quantities. Engelmann observed this many years ago on ciliated cells, but he did not try to explain it. Also as regards the nervous system we know with regard to chloroform and ether that, when administered, they first cause excitement and afterwards insensibility. So far as we know, this contrast has never been explained, but when viewed in connection with our experiments, the phenomenon becomes clear. In the beginning of narcosis only small quantities have entered into the nerve cells. The consequence is a softening in the first place of the outer layer. This weakened state of the cells produces an

increase of activity (amœboid motion?). Later, when a greater amount of the substance has been taken in, the paralysing effect gets the upper hand. With alcohol the same experience is well known.

In following this point we are led to think of the remarkable influence of a sojourn in high mountain regions, on metabolism, on sleep, and on the state of the mind. The cause is entirely unknown. It has been proved that these phenomena are not due to the height as such, for in balloons they do not occur, nor are they found in high mountain regions, but when examining where they are observed, we find that it is in the neighbourhood of coniferous woods. So we are inclined to think that it is due to the stimulating effect of the odour of resin (turpentines, etc.) on the nerve-cells.

Prof. Sherrington and Miss Sowton, in their studies on the dosage of the mammalian heart by chloroform, found that, especially with greater amounts of the drug, it was usual for the first effect of the administration to be a distinct though slight increase in amplitude of the contractions. After cessation of the administration of the drug in moderate dose, it was not unusual before the recovery of the beat for the heart to pass over for a short time into a condition of super-activity. These phenomena suggest an irritative excitatory effect of small doses of the substance on muscle or nerve-fibres (or both) of the heart. These results agree with those previously obtained by Prof. A. D. Waller in his experiments with the isolated nerve.

There are experiments also with other organs which may be considered in the same light. Thus Prof. J. Loeb discovered that substances dissolving fat have the power of rendering possible the parthenogenetic development of eggs. Now we may imagine, with Loeb, that the substance dissolves in a lipoid of the outer layer of the egg, thus giving rise to the formation of a fertilising membrane. We think we may safely go one step further and assume that it is owing to the weakening of the membrane that the movement of the protoplasm underlying every cell division manifests itself. This view is confirmed by the observation of Prof. R. S. Lillie, who saw also that by a short transitory raising of the temperature in the eggs of starfishes a typical fertilising membrane may be formed, which formation is followed by the development of part of the eggs into larvæ. J. Loeb was able to confirm this for Medusæ.

After consideration of the foregoing facts and suggestions, we were inclined to think that the stimulating effect of traces of substances which dissolve fat on the activity of cells is a widespread phenomenon. Hence we have investigated whether this influence might also be seen in *plant-cells*. To do so, we chose the germination of seeds, a process in which a considerable division and growth of cells manifests itself. The seeds we chose were grains of wheat, and for the fat-solvent we took chloroform. With chloroform, 1 part to 100,000, an important acceleration in the germination was observed; chloroform 1 to 1000, on the contrary, impaired the germination, evidently because a second factor made itself felt, viz. paralysis of the protoplasm. Later I heard that in practice the growth of snowdrops is promoted by ether. In recent times Chiari succeeded in forcing blossoms to a considerable extent by ether-vapour, and Mansfield the germination of pumpkin-seeds by vapour of alcohol and ether.

Hence it is clear that the observations on phagocytosis deserve our attention on general grounds as well as special. We do not at all mean to say that all substances dissolving fat have the same effect on cells of all kinds; far from it. I would emphasise that, in order to be brief and to avoid complexity of detail, I have here presented the matter somewhat simpler than it really is. Nor have all the suggestions here made towards explaining facts regarding other cells than phagocytes been actually proved. Without hypothesis, science cannot progress. Fortunately we need not stay in error for long, for we can always appeal to the supreme judge, experiment.

This account of results and views, the fruit of some years' work with several collaborators (Hekma, de Haan, etc.),[2] being of necessity incomplete, I have attempted to select what may specially interest the general scientific reader.

We are continuing our study of the biology of phagocytes, and each day we become more convinced of their excellence as a simple object, for the study of problems of a general biochemical nature, and for some of practical interest as well.

H. J. HAMBURGER.

IRELAND'S INDUSTRIAL OPPORTUNITIES.

A LECTURE delivered in April last before the Insurance Institute of Ireland by Mr. George Fletcher, the assistant secretary of technical instruction, and recently issued in pamphlet form, deserves the serious attention of all well-wishers of Ireland. We have in Ireland a population little more than half of what it was in 1841, and which is now annually depleted by emigration to such an extent that any increase in its population is well-nigh impossible.

It is obviously, therefore, of the highest possible importance to the well-being, not merely of Ireland, but also of the kingdom generally, that means should be taken to ensure the utmost development alike in agriculture as in manufactured products, since it is now clearly realised that it is only by a combination of both that the well-being of Ireland can be firmly established.

The Department of Agriculture and Technical Instruction established in 1899, mainly through the strenuous efforts of Sir Horace Plunket, the first vice-president, has done much for the promotion of agriculture and its products and of manufacturing industry. Improved methods have been introduced into farming, fishery, and industrial operations, especially in the latter case by the encouragement of cottage industries, with a view to find employment for the rural population in times and seasons not devoted to agricultural work, and with a view also to add to the interest of an otherwise monotonous life.

Large sums have been spent as a result of local and Governmental effort in the promotion of technical education, with the result that now practically all over Ireland facilities exist for the due training of the workers engaged in agricultural and industrial pursuits. At the same time, the Department has persistently urged the necessity, if technical training is to be of any real value, of a better and more pervading system of elementary and secondary education upon which to found it, and also for the reason that it is desirable to widen by means of a sound general education the mental horizon of the people.

Believing that no permanent good can be ensured except by the co-operation of the people themselves, it has been the aim of the Department to encourage the formation of associations of farmers and manufacturers, so as to secure a sense of solidarity and of common effort.

[2] A full account of the researches as far as the year 1912 can be found in my monograph "Physikalisch chemische Untersuchungen über Phagozyten. Ihre Bedeutung vom allgemein biologischen und pathologischen Gesichtspunkt." (Wiesbaden: J. F. Bergmann, 1912.)

The example of Denmark has proved a potent influence in the measures which have been taken to develop the agricultural resources and products of Ireland. The export value of eggs, butter, beef, mutton, pork, bacon, and hams from Ireland was in 1912 11,820,356*l.*, but in 1913 we received from Denmark alone butter, eggs, and bacon to the value of nearly twenty-two millions sterling.

It cannot be said that this huge difference in value is attributable to a better soil or climate, and, as a matter of fact, it is entirely due to the better education of the people, to a more scientific treatment of the soil and of the animals concerned, and to a stronger sense of the advantages of co-operative effort. It is clear that given these conditions, Ireland, with its much larger acreage and more productive soil, could raise for export the greater part of this importation of food products; and as with agriculture, so with the smaller factory and cottage industries. It is made clear in Mr. Fletcher's address that there is abundant scope for their establishment and development, of which Belgium affords a striking and pregnant example, which the people of Ireland would do well to follow, and thus bring the small town and the countryside into close and harmonious relation.

J. H. REYNOLDS.

AEROPLANE STABILITY.

SOME phases of fore-and-aft or longitudinal equilibrium in flying are discussed by Dr. Orville Wright in a recent publication of the Smithsonian Institution, entitled "Stability of Aeroplanes." Although a beginner finds most difficulty in mastering the lateral control, it is his lack of knowledge of certain features of the fore-and-aft equilibrium which leads to most of the serious accidents.

In an ideal flying machine the centre of gravity would lie in the line of the centre of resistance to forward movement and also in the line of thrust, but in practice this is not always feasible, since the machine must be built to land safely as well as to fly. In flying, a low centre of gravity—that is, one below the centre of support, causes an oscillating movement about the lateral axis like that of a pendulum. On the other hand, a high centre of gravity tends to cause the machine to roll over in landing, and consequently a compromise is adopted.

The two principal methods used in preserving fore-and-aft equilibrium have been the shifting of weight so as to keep the centre of gravity in line with the changing centre of lift, and the utilisation of auxiliary surfaces, known as elevators, to keep the centre of pressure in line with a fixed centre of gravity. The first method has been found impracticable on account of the impossibility of shifting large weights quickly enough, but the second is used in most of the modern flying machines.

Flying machines of the latter type should have their auxiliary surfaces located in the front or rear as far as possible from the main bearing planes, because the greater the distance the greater is the leverage, and consequently the smaller the amount of surface required. No part of either the main surface or auxiliary surface should be exposed on their upper sides in a way to create a downward pressure for maintaining equilibrium.

The downward pressure of air is used to some extent, however, on account of its adaptability, in producing more or less inherent stable aeroplanes. Dr. Wright describes an aeroplane in which equilibrium is maintained by an arrangement of surfaces so placed that when a current of air strikes one part of the machine, creating a pressure that would tend to disturb the equilibrium, the same current striking another part creates a balancing pressure in the opposite direction. This compensating or correcting pressure is secured without the mechanical movement of any part of the machine. While this system will control a machine to some extent, it depends so much on variation in course and speed as to render it inadequate to meet the demands of a practical flying machine.

In order to secure greater dynamic efficiency and greater manœuvring ability, auxiliary surfaces mechanically operative are used in present flying machines instead of the practically fixed surfaces of the inherently stable type, but they depend to a greater extent upon the skill of the operator in keeping equilibrium. If the operator were able to "feel" exactly the angle at which his aeroplane meets the air, at least 90 cent. of all aeroplane accidents would be eliminated. Instruments for this purpose have been produced, but they are not in general use. The average flier does not realise how dangerous it is to be ignorant of this angle, nor does he know when he is "stalling." By "stalling" Dr. Wright means coming to rest in the air, or nearly so.

The danger from "stalling" comes when the operator attempts to check the machine's downward plunge by turning the main bearing surfaces to still greater angles of incidence, instead of pointing the machine downward, at a smaller angle of incidence, so that the speed can be recovered more quickly. Most of the serious accidents in flying occur, after long glides from considerable heights with the power reduced, when an attempt is made to bring the machine to a more level course several hundred feet in the air. The machine quickly loses its speed and becomes "stalled." Those who have seen the novice make a "pancake" landing have seen the beginning of a case of "stalling" which might have been fatal had it taken place at a height of 100 or 200 ft. in the air.

The greatest danger of flying comes from misjudging the angle of incidence. If a uniform angle were maintained, there would be no difficulty in securing fore-and-aft equilibrium. Experiments made during the past year or two have brought about a considerable advance in the development of automatic stability. A device described by Dr. Wright comprises a small horizontal wind-vane so mounted on the machine as to ride edgewise to the wind when the machine is flying at the desired angle of incidence. In case the machine varies from the desired angle, the air will strike the vane on either its upper or lower side. The slightest movement of the vane in either direction brings into action a powerful mechanism for operating the controlling surfaces. If the wind strikes the vane on the underside the elevator is turned to cause the machine to point downward in front until the normal angle is restored, and if the air strikes the vane from above, an opposite action upon the elevator is produced. The author maintains that a machine so controlled is not liable to "stalling." Another method for maintaining fore-and-aft equilibrium utilises the force of gravity acting on a pendulum or tube of mercury, and a second employs the gyroscopic force of a rapidly revolving wheel. In both these systems, however, the angle of the machine is regulated with reference to the horizontal, or some other determined plane, instead of the angle of the impinging air. Other faults render the pendulum and mercury tube useless in regulating fore-and-aft equilibrium, although the pendulum is found to be useful in regulating the lateral stability.

MINERAL INDUSTRY OF CANADA.

THE Canadian Department of Mines has issued, almost simultaneously, the annual report on the mineral production of Canada during the calendar year 1913 and the preliminary report on the mineral production of Canada during the calendar year 1914. Neither of these reports presents any feature of outstanding interest, except that the effect of the war upon the mineral industry of Canada is here made evident. The value of the output in 1913 showed an increase of 7·84 per cent. upon that of the previous year, whilst that for 1914 shows a decrease of 11·8 per cent. from that of 1913. It is, of course, not absolutely clear that the decrease is wholly due to the war. For example, the silver production of Canada, which showed a slight decrease already in the former year, has fallen about 16 per cent. in the latter year; the silver production is due in very great measure to the output of the Cobalt district, Ontario; in 1904, when the production of this district commenced, the annual production of silver was 3½ million ounces, whereas in 1910, when it reached its maximum, it was nearly thirty-three million ounces, and silver ranks second in total value only to coal amongst the mineral products of Canada, having amounted to 14·4 per cent. of that total in 1913. Both the amount of silver and the grade of the ore got in the Cobalt district have shown a gradual decline of recent years, and there appear to be some reasons to suppose that the life of the mines in this district is not likely to be a long one. A decrease in silver production might therefore have been expected normally, and it is quite possible that the part played by the European war in the recorded decrease is not an important one. Other decreases, such as those in coal, pig-iron, cement, and clay products, are, on the other hand, to be referred in all probability entirely to the war crisis. The three former showed substantial increases in 1913 over the previous year, and although the clay products fell off in value in that year, this was due merely to a temporarily decreased demand for brick, owing to the unfavourable financial position, which seriously limited building operations in the Dominion. A careful study of the two reports indicates no ground for supposing that the mineral industry of Canada is in other than a thoroughly sound condition, or that its expansion in the future will be unable to keep pace with any demands that may be made upon it.

EXPLOSIVES.

THE Smithsonian Institution, Washington, has recently issued an article by Major Edward P. O'Hern, of the Ordnance Department, U.S. Army, which deals with the composition, methods of employment, and results obtained with explosives.

The author divides explosives into three classes: progressive or propelling explosives, known as low explosives; detonating explosives or high explosives; and detonators or fulminates. For all classes the effect of the explosion is dependent upon the quantity of gas and heat developed per unit of weight and volume of the explosive, the rapidity of the reaction, and the character of the confinement, if any, given the explosive charge. The rapidity of reaction varies greatly with different explosive substances and with the manner in which the explosion is started.

Black gunpowder, smokeless powder, and black blasting powders are known as low explosives, for certain of which, such as smokeless powder, the explosion does not differ in principle from the burning of a piece of wood or other combustible. The combustion is very rapid, but is a surface action proceeding from layer to layer until the grain is consumed. Such materials are known as low or progressive explosives, although the total power developed through the combustion of a unit weight may be very great, and would be destructive unless properly controlled.

In high explosives, such as dynamite, nitroglycerin, gun-cotton, some blasting powders, and most of the "permissible explosives" approved by the U.S. Bureau of Mines for use in mines where gas explosions are liable to occur, the progress of the explosive reaction is not by burning from layer to layer, but the breaking up of the initial molecules gives rise to an explosive wave which is transmitted with great velocity in all directions throughout the mass, and causes its almost instantaneous conversion into gas. The velocity of propagation of the detonating wave has been determined for some materials to be more than 20,000 ft. per second, or approximately four miles per second; this form of material is used in shells and for bursting purposes. The progressive emission of a gas from a low explosive, such as burning gunpowder, produces a pushing effect upon a projectile, whereas the sudden conversion of an equal weight of material into gas, as would happen with a high explosive such as dynamite or nitroglycerin, would develop such high pressure and shattering effect as to rupture the gun.

The action of fulminates is much more brusque and powerful than that of the high explosives. Since they can be detonated by shock or the application of heat, they are used in primers and fuses to start action in both low and high explosives. The most important is fulminate of mercury, which produces a pressure of about 48,000 atmospheres.

At no time in the history of the world have explosives played such an important part in deciding the destiny of nations as they are playing to-day in the prosecution of the present war. Their extensive use in the mighty engines of destruction, such as the submarine mine, the torpedo, and in projectiles thrown from cannon to great distances with marvellous accuracy, is resulting in loss of life and destruction of property on an unprecedented scale.

Beginning with black powder, the earliest record of which in actual war was in the fourteenth century, the author follows the development of powder through its early stages of brown powder to the two principal forms of smokeless powder for military purposes—nitro-cellulose and nitro-glycerin—stating that the use is quite evenly divided; the U.S. Army and Navy, the French Army and Navy, and the Germany Army using the former, and the British Army and Navy and the German Navy using the latter. He then gives much detailed information concerning the manufacture, life, source of supply, and tests of smokeless powder manufactured from nitro-cellulose or gun-cotton. Following which, subjects relating to life of guns, bursting charges for projectiles, armour-piercing projectiles, high explosive shells, shrapnel, fuses, aeroplane bombs, means of igniting explosives, mines, torpedoes, and the storage and shipment of explosives in the United States are discussed.

THE BONAPARTE FUND FOR THE YEAR 1915.

THE committee appointed to consider the requests for assistance from this fund have examined twenty applications, and made the following proposals, which were accepted by the Academy:—

3000 francs to Auguste Lameere, professor at the University of Brussels, to assist him to continue his researches at the zoological station of Roscoff.

4000 francs to M. Le Morvan, assistant astronomer

at the Paris Observatory, for the publication of the photographic and systematic chart of the moon.

2000 francs to Paul Vayssière, to assist him in the continuation of his researches on cochineal insects.

3000 francs to M. de Zeltner, as a contribution to an expedition he proposes to make in the Sudanese Sahara, more particularly in the Aïr massif.

2500 francs to L. Bordas, to aid in his investigations relating to insects which attack forest trees, and more especially of those species now causing great damage in the woods of the Central Plateau and the west of France.

3000 francs to Joseph Bouget, for realising his cultural experiments on a larger scale, with reference to the afforestation and improvement of pastures in the Pyrenees.

3000 francs to Henry Devaux, for the continuation of his researches on the cultivation of plants in arid or semi-desert regions.

2000 francs to Victor Piraud, to enable him to continue his studies on the fauna of torrents and Alpine lakes, particularly at high altitudes.

2000 francs to M. Tiffeneau, for the continuation of his studies on the phenomena of molecular transposition in organic chemistry.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The following awards at Newnham College have been made:—An associates' fellowship of 100*l.* for three years, tenable from October, 1915, to Miss Ruth Holden, who proposes to continue her work in fossil botany; a Mary Ewart travelling scholarship of 300*l.*, divided between Miss H. J. Hartle and Miss M. N. L. Taylor; the Mary Ewart scholarship of 100*l.* for three years to Miss K. M. Tillyard; the Marion Kennedy studentship of 100*l.* to Miss E. E. H. Welsford; the Gilchrist studentship of 100*l.* to Miss C. Stoney; a Bathurst studentship of 75*l.* to Miss M. W. Jepps; the Harkness studentship of 70*l.* to Miss E. W. Gardner; the Arthur Hugh Clough scholarship to Miss P. M. Sargent.

LEEDS.—The William Walker scholarship, of the annual value of 90*l.*, for the scientific study of leather with a view to its subsequent application to industrial development, and the William Walker exhibition for instruction in the technology of coal and its by-products, are announced. The endowments have been founded in memory of the late William Walker, of Whitehaven, by his widow and two sons, who have placed 4500*l.* in trust for the purpose.

THE Institution of Naval Architects' scholarship, value 100*l.* per annum, and, subject to the regulations governing the same, tenable for three years, has been awarded to T. S. D. Collins.

MR. G. H. SHULL, of the staff of the Station for Experimental Evolution, Cold Spring Harbour, Long Island, has been appointed professor of botany and genetics at Princeton University, Princeton, New Jersey.

THE issue of the *Lancet* for August 28 is the "Students' Number," devoted almost entirely to information respecting the medical examining bodies and the courses of instruction given in the various medical schools and colleges of the United Kingdom.

THE following appointments to the Indian Educational Service have been made by the Secretary of State for India:—Mr. Harold Tinker, professor at the Training College, Allahabad; Mr. G. H. Geach, principal of the Training College, Peshawar; Mr. W. Saunders, professor of chemistry in the Civil Engineering College, Sibpur, Bengal; Miss E. E. Spencer, inspectress of schools in the United Provinces.

AN examination in biological chemistry, bacteriology, fermentation, and enzyme action will be held in connection with the Institute of Chemistry, beginning on October 18. The list of candidates will close on September 14. An examination in chemical technology will be held in October, but the actual date will be announced later. Notification from intending candidates must be received by September 14.

WE are informed that Mr. E. Lovett, who has formed a collection of children's toys, playthings, and games, has presented the collection to the Borough Council of Stepney, and that it is to be exhibited at the Whitechapel Museum. It will be arranged in ten sections, viz., locomotion and transport, dolls, animals, habitations, farming and agriculture, mining, manufactures and commerce, the household, playthings, games, sundries, *i.e.* toys and games of antiquity; toys made of natural objects, such as shell, bone, stone, nuts, etc.

THE Department of Agriculture and Technical Instruction for Ireland has issued a number of pamphlets in preparation for the work of the coming academic year. These include the "Programme for Technical Schools and Classes," in which it is pointed out that the regulations for technical schools and classes which were in operation during the session 1914–15 will continue in force during the session 1915–16. The "Programme of Experimental Science, Drawing, Manual Instruction, and Domestic Economy for Day Secondary Schools" has undergone no alteration, and the work next year will follow on the lines previously laid down. The "Special Course in Experimental Science: Physiology and Hygiene" has been revised.

THE Education Committee of the Staffordshire County Council has issued its "Directory for Higher Education, 1915–16." The directory contains the regulations of the committee and details of schemes in operation throughout the administrative county. Owing to the necessity of publication before the commencement of the new session it has not been possible to make final arrangements with regard to some of the classes, and, as the directory points out, some readjustments and alterations may be necessary later. One or two typical instances of the thoroughness with which the committee has provided for the needs of the county in higher education may be given. On account of differences of character between the North and South Staffordshire coalfields, and for other reasons, separate schemes of instruction in mining have been worked out for the two districts. Such instruction in the North Staffordshire coalfield is provided by the County Education Committee and the Education Committee of Stoke-on-Trent working in co-operation. The principal centre at which instruction is given is the Central School of Science and Technology, Stoke-on-Trent. This is a specialised school adapted to the needs of potting and mining, the principal industries of the district, and equipped for the study of the technology of these industries up to the most advanced grade. In South Staffordshire a general scheme of instruction in mining is designed to extend over six years, and classes in connection with it are held at several centres. At the new County Metallurgical and Engineering Institute, Wednesbury, theoretical and practical classes are held in metallurgy, iron and steel manufacture, and subjects related to engineering. Other branches of technological science in which special facilities have been provided are:—Pottery and porcelain manufacture, boot and shoe manufacture, silk manufacture, and horticultural and smaller agricultural industries.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 23.—M. Ed. Perrier in the chair.—G. **Humbert**: The reduction of the forms of Hermite in an imaginary quadratic body.—MM. **Costantin** and **Bois**: Three types of commercial vanilla of Tahiti. Since three-fifths of the world's production of vanilla comes from the French colonies, the question of its culture is worthy of investigation. The fruit from Mexico and Reunion is superior to that of the Tahiti type. In the present note a comparison is made between the types of vanilla known under the names of Mexico, Tahiti, and Tiarei, and some practical suggestions are made for cultivation.—Paul **Vuillemin**: The staminal origin of the perigon of the Liliaceæ; proofs furnished by the flowers of Hemerocallis.—E. F. **Perreau**: An electro-vibrator worked with interrupted currents. Previous types of this instrument, used in surgical work, have been worked with an alternating current, but an interrupted continuous current may be also used with advantage. Details of the arrangement are given, which, for the detection of non-magnetic bodies, is superior to the original instrument.—Daniel **Berthelot**: The co-volume of the gases disengaged by explosive materials. The co-volume b, in the equation $p(v-b)=RT$, is usually taken as 0·001 in calculations relating to explosives. It is now shown that this only holds for gases the critical temperature of which is sensibly equal to four times the critical pressure.—M. **Guilbaud**: An apparatus for the photolysis of powders.—J. **Repelin**: The Cretaceous age (Begudian) of the detritic layers of Logis de Nans (Var).—Henry **Hubert**: Subterranean waters in western Africa. A chart of Senegal is given showing the depths of the underground water.—Jules **Amar**: Arthrodynamometric measurements. — H. **Vincent**: Typhoid toxin and the production of a specific serum against typhoid fever. A study of the conditions for obtaining cultures of high toxic power.

WASHINGTON, D.C.

National Academy of Sciences, August 15 (Proceedings No. 8, vol. i.).—J. **Loeb**: Weber's law and antagonistic salt action. The author had shown that the ratio of the concentrations of antagonistic ions must remain within certain limits for the normal functioning of an organism. It is here shown that these limits remain approximately constant as the concentration of one of the ions is changed.—E. L. **Nichols** and H. L. **Howes**: The polarised fluorescence of ammonium uranyl chloride. The remarkable fluorescence spectrum of this salt is described in considerable detail, observations being made at $+20°$ C. and $-185°$ C.—T. **Michelson**: The linguistic classification of Potawatomi. By study of the so-called verbal pronouns, which afford most satisfactory classificatory criteria, it is shown that Potawatomi belongs to the Ojibwa group of Central Algonquian dialects.—H. **Shapley** and Martha Betz **Shapley**: The light curve of XX. Cygni as a contribu- to the study of Cepheid variation. The form of the maximum of brightness in XX. Cygni is variable from period to period, and thus suggests the hypothesis that the periodic light and spectrum variations in this and other Cepheid variables should be ascribed to internal vibrations producing irregularities in luminosity instead of to double-star phenomena.—C. B. **Davenport**: The feebly inhibited. III.—Inheritance of temperament, with special reference to twins and suicides. A statistical study on eighty-nine family histories, affording 147 matings, leads to the conclusion that temperament is inherited as though there were in the germ plasm a factor E, which induces the more or less periodic occurrence of an excited condition and its absence, *e*, which results in a calmness; also a factor C which makes for normal cheerfulness and its absence, which permits a more or less periodic depression, the factors behaving as though in different chromosomes, so that they are inherited independently.—H. **Shapley**: Second-type stars of low mean density. Because of its bearing on the question of the order of stellar evolution, the density of stars of the second spectral type is discussed from the point of view of the dependability of the observational and theoretical work that is the basis of the derivation of occasional extremely low values.—W. H. **Brown** and Louise **Pearce**: The pathological action of arsenicals upon the adrenals. That arsenicals of diverse chemical constitution exert pronounced pathological action upon the adrenals has not been generally recognised. It appears from these observations that the adrenotropic action of arsenicals is one of the most constant and important features of arsenical intoxication, and it is suggested that therapeutic doses of some arsenicals may be found to produce definite stimulation of the adrenal glands.—Louise **Pearce** and W. H. **Brown**: Variations in the character and distribution of the renal lesions produced by compounds. Not all compounds of arsenic produce vascular lesions; some are capable of producing tubular nephritis; the difference in the pathogenic action being explainable only upon the basis of the chemical constitution of the different compounds of arsenic.—H. S. **White**: Seven points on a twisted cubic curve. If seven points on a twisted cubic be joined, two and two, by twenty-one lines, then any seven planes that contain these twenty-one lines will osculate a second cubic curve.

CAPE TOWN.

Royal Society of South Africa, July 21.—Dr. L. Péringuey, president, in the chair.—S. H. **Haughton**: Exhibition and description of a new type of fossil reptile from the Karroo. A somewhat incomplete skull, with associated limb-bones and vertebræ, from the upper Tapinocephalus zone of the Beaufort West District were exhibited. The form seems to show affinities both with the Dinocephalia and the Gorgonopsia. In the general form of the skull and of the palate it recalls the Dinocephalia, although it is much smaller, and its maxillary and premaxillary teeth are herbivorous, like those of Tapinocephalus and other forms; but in the possession of a few small palate teeth, in the vertical occipital plate, the shallowness of the basicranium and some other features it recalls the Gorgonopsia. The form occurs in beds which contain members of both groups, although the larger Dinocephalia of lower horizons seem to have given place to smaller forms. Watson has contended that these two groups have arisen from a not very far distant common ancestor; and although this form cannot be looked upon as ancestral, it throws some further light on the relationships between the two groups.—K. H. **Barnard**: Conus shells illustrating variation in markings. A series of shells was exhibited, showing gradation in the pigment from a condition in which the coloration is strongly marked to that in which the shells are practically colourless. The question of the origin of the pigment in its relation to the environment and heredity of the mollusc was discussed.—S. J. v. d. **Lingen**: (1) Simple apparatus for finding "G"; (2) simple apparatus for standardising a given vibrator. Apparatus was described the use of which does not involve assumptions of dynamical quantities that the student cannot determine for himself, and which is adapted to give him some definite idea about the acceleration of a freely falling body. A piece of apparatus was also described by which velocities and accelerations of trolleys, etc., can be determined without the need of assuming the

time of vibration of some vibrator.—J. K. E. **Halm**: Astronomical photometry. An account was given of a method which claims to derive from the measured diameters of the star discs on a photographic plate the brightness or "magnitude" of any star on a self-consistent basis. The work is founded on the examination of the properties of the photographic plate in the light of experiments made by Abney and Kron. The results obtained for the stars of the Cape astrographic zones demonstrate a perfect agreement of the Cape system with the Harvard photographic system. Comparisons between the photographic and visual magnitudes lead to the conclusion, also in agreement with the Harvard results, that the "colour" of the stars is a function of their brightness, faint stars being slightly redder than bright stars. This fact is tentatively attributed to the existence of absorbing matter in space. The phenomenon is emphasised in the regions of the galaxy. It is also found that, on the average, stars are actinically brighter in the Milky Way than in other regions. —W. A. **Jolly**: The electromotive changes accompanying activity in the mammalian ureter.—I. B. Pole **Evans**: A new aloe from Swaziland. A new species of aloe, found in Swaziland by Mr. R. A. Davis in June, 1914, was described and named *Aloe suprafoliata*. It may be recognised by its distichous leaves, which are rigid, somewhat fleshy, and patent or gracefully recurved. The flower spike is slender, unbranched, and bears rather loosely-attached rose doree flowers. The plants are usually found on the tops of quartzite kopjes, and have been found at Stegi, Lebombo Range, and Forbes Reef.

CALCUTTA.

Asiatic Society of Bengal, August 4.—S. C. **Mitra**: North Indian charms for securing immunity from the virus of scorpion-sting. Charms which are popularly supposed to render the user thereof either invulnerable to the stings of scorpions or immune from their virus, *e.g.*:—(1) By the repetition of certain passages of the Koran; (2) by performing the fire-walking ceremony known as *Dam madār;* and (3) by carrying about one's person the medicinal plant known as the *Chirchirā* (*Achyranthes aspera*). The author also described the preparation and discussed the origin of a curious cognate charm whereby a practitioner acquires the power to cure scorpion stings, after rubbing with his hands, while he is in a blindfolded state, the blossoms of a mango tree.—I. H. **Burkill**: The Terai Forests between the Gandak and the Tista.—Dr. N. **Annandale**: The origin and distribution of the fauna of the Lake Tiberias. The aquatic fauna of the Jordan river-system, and in particular that of the Lake of Tiberias, consists mainly of species belonging to Palæarctic genera, and closely allied to, if not identical with, forms from eastern Europe or from the Euphrates Valley. There are, however, a certain number of animals that are Ethiopian either in genus or species. It is a remarkable fact that the distinctly Ethiopian forms are all fish. There are a considerable number of endemic species in the Lake of Tiberias, but none of them are very highly specialised. The only endemic genus is the sponge Cortispongilla. The presence of African fish can only be explained by a former connection through the south of the system with the "Erythræan River" of Gregory, which received a tributary from Central Africa. The fish of African origin all belong to families and genera that are particularly suited to survive unfavourable conditions. The view is put forward that they have been able to survive great changes of salinity in the water of different parts of the Jordan system, while any African invertebrates that may have made their way into it have perished, with the possible exception of a few very widely distributed mollusca (such as *Melania tuberculata*) and other forms that exist in tropical Asia as well as in Africa.—S. C. **Banerji**: A botanical curio. A huge epiphytic *Ficus bengalensis*, L., on a tall *Borassus flabellifer*, L., is to be found in the village Barā on the way to Pāthrole from Madhupur (Sonthal Parganas). The two together appear to be a composite tree. One-half of the height of the palm from the ground, excepting a small portion at the base, is completely encased by the root of the fig. The persistence of the epiphytism is interesting.

SOLAR MYTHS.

Sun Lore of All Ages. A Collection of Myths and Legends Concerning the Sun and Its Worship. By W. T. Olcott. Pp. xiii + 346. (New York and London: G. P. Putnam's Sons, 1914.) Price 10*s.* 6*d.* net.

IN the preface it is stated that the author, during the compilation of a volume on "Star Lore of All Ages," found a wealth of interesting material pertaining to the mythology and folk-lore of the sun which seemed worth putting together in a separate volume, including the legends, traditions and superstitions which all ages and nations have woven about the sun.

The author seems to have gathered his materials from a number of works on mythology and folk-lore, from which he frequently gives verbatim extracts. Outside this subject he does not appear to have made any special study of the general rise and progress of civilisation, as he sometimes makes curious mistakes. For instance, he tells us (p. 137) that Anaxagoras was put to death on account of his scientific opinions. But a worse fault is that no attempt is made to systematise the immense amount of legends and stories he has collected. The reader is repeatedly carried from India to North America, thence to Finland and *viâ* Greece to Scandinavia and back again. And the author has not avoided the snare in which so many students of folk-lore have been caught, by making simply every myth, fable or tale he has met with into a solar myth, from Jack-the-Giant-Killer to Jonah, Cain, the Homeric poems, and so *ad infinitum.* Needless to say, this process often involves very far-fetched explanations. Thus the Royal Arms of England, "supported by the solar lion and the lunar unicorn," are made to express solar worship. We do not quite know what to make of the following curious statement (p. 173):—

"The resemblance between the lives of the Sun-God Phœbus Apollo and Jesus Christ, the central figure and Exemplar of the Christian religion, is striking. The circumstances of their birth were in many respects similar, in that they were born in comparative obscurity. . . . For a while Phœbus Apollo hid his greatness in a beggar's garb. . . . This mode of existence was in every way similar to the life of Christ. . . . Although the Sun-God's death at nightfall is ignominious, akin in this respect to the crucifixion, still its predominant feature is one of glory, and the reappearance of the triumphant sun after death is in every way typical of the resurrection, thus portraying in a startling manner the completeness of the analogy between the lives of Christ and Apollo."

Has the author ever heard of Dupuis and his "Origine de tous les cultes"? Probably not, as he only quotes books written in the English language. But Dupuis in his voluminous work proved to his own satisfaction that the founder of the Christian religion had never existed: he was only a solar myth, identical with Bacchus, Osiris, and Hercules. It is safer to be cautious in drawing parallels between fact and fiction and in looking everywhere for solar myths. But all the same, even a critical reader will find much to interest him in the accounts of sun-worship and sun-myths given in this volume, not least in the numerous extracts from the publications of the United States Bureau of Ethnology. The book is beautifully illustrated with thirty plates taken from paintings or giving views of sun temples and worship.

POCKET ENCYCLOPÆDIAS OF PETROLEUM AND CHEMISTRY.

(1) *Petroleum Technologist's Pocket-Book.* By Sir Boverton Redwood, Bart., and Arthur W. Eastlake. Pp. xxiv + 454. (London: Charles Griffin and Co., Ltd., 1915.) Price 8*s.* 6*d.* net.

(2) *The Chemists' Year-Book,* 1915. Edited by F. W. Atack. Two vols. Vol. i., pp. 354. Vol. ii., pp. 355–914. (London and Manchester: Sherratt and Hughes, 1915.) Price 10*s.* 6*d.* net.

(1) THE names of Sir Boverton Redwood and Mr. Arthur W. Eastlake on the title-page of the "Petroleum Technologist's Pocket-Book" would alone be an ample guarantee that thoroughness of treatment and completeness of content would be found in its pages, and the work fully bears out the expectation arrived at. It is indeed a miniature edition of Sir Boverton Redwood's monumental work on petroleum, and in its 454 pages of pocket-book size contains more useful information, tables, and data referring to every branch of the mineral oil industry than it would be thought possible could be got into a portable form.

Starting with the origin and occurrence of petroleum in the earth's crust and its geographical distribution, prospecting for petroleum is next dealt with, and much useful information is given as to licences, mining leases, and regulations in various parts of the world.

Part ii. is geological, and contains definitions of various geological terms and the identification of rocks and strata illustrated in the coloured frontispiece of the succession of the stratified formations of the earth's crust. This part also contains many useful tables for horizons, angles of dip, natural sines, cosines, and tangents, quantities of oil per acre for given thicknesses of oil sand, and a host of other useful data.

Part iii. is chemical and physical, giving the specific gravities of crude oils, products, analyses, viscosity, calorific value, specific heat, and the composition of various purifying agents; whilst Part iv. treats of oil production in all its phases. Part v. embraces refining, transport, storage and testing of oils, and the next division goes fully into the uses of petroleum and its products. Part vii. is a mass of information on weights, measures, and other useful data connected with oil, whilst Parts viii. and ix. deal with miscellaneous information and statistics, brought down in most cases as late as 1913, and forming a fitting conclusion to a book which no one in any way interested in oil can afford to be without.

(2) Another extremely useful work is "The Chemists' Year-Book for 1915," compiled by Mr. F. W. Atack, of the Technical Department of Manchester University, and designed to take the place of the voluminous German publications, of which the English chemist has been forced to avail himself in the absence of any complete and up-to-date English collection of chemical data.

In order to secure portability it is published in two volumes—the first, a pocket-book containing a diary, all the more important details of qualitative, volumetric, gas, ultimate, electro-chemical and spectrum analysis, together with tables of the general properties of inorganic and organic substances, useful memoranda, conversion and logarithm tables.

The second volume, which from the absence of a flap is evidently intended more for reference, gives every possible table on the physical constants of gases, liquids, and solids, properties of minerals, and finally a really excellent summary of more technical processes, in which fuel and illuminants, acid and alkali manufacture, oils and fats, brewing, coal tar and its derivatives, synthetic dye-stuffs, and many other manufacturing processes find place.

It is refreshing to find, at a time when so much is being written and said as to the capture of German trade, that so practical a first step has been taken, and every working chemist will welcome this year-book, containing as it does in convenient form 900 pages of most useful data.

GEOGRAPHIC INFLUENCES AND THE OLD TESTAMENT.

Geographic Influences in Old Testament Masterpieces. By Prof. Laura H. Wild. Pp. xiii + 182. (Boston and London: Ginn and Co., 1915.) 4*s.* 6*d.*

THE book aims at showing how the physical environment and geographical conditions of a nation are expressed in its literature and history. This fact, notwithstanding its great importance, has been too often forgotten by teachers and perhaps in no case more frequently than in dealing with the older portion of the Bible. One cause of this has been a tendency, with a large section of the Christian church, to regard its older books with an unreasonable reverence, and forgetting that they are the history of a people, who, though the chosen means for imparting great truths to the world, were men and women like ourselves, even the best of whom were liable to human weaknesses. The authoress accordingly seeks to enhance the attractions of Bible teaching by linking its more interesting episodes with the main geographical features of the country—its coastal plain on the one side, and its inland desert on the other, its valleys and its hills —Carmel, Gilboa and Tabor, the cedar-clad slopes of Lebanon and the snowy dome of Hermon, from which the Jordan begins its course, in some respects unique, to its grave in the Salt Sea.

The intention of the book is excellent, but we cannot say so much for its execution. Prof. Laura Wild's comments seldom rise above the commonplace, and we find among them little or no evidence of a personal knowledge of Palestine. For descriptions of its scenery she seems to depend upon quotations from well-known travellers, so that we miss those little graphic touches which add to the life and interest of an account. To some statements also we must take exception, such as that Joseph was "little" when sold into Egypt, for he was over seventeen; that Heber can be described as an Israelite, and that Endor is near the Sea of Galilee. Her knowledge also of natural history and geology leaves something to be desired. It is misleading to call the cyclamen a native of Palestine, for the genus has a wide range, one species being claimed as British, which is at any rate common in many parts of Europe. The lion which Benaiah killed in a cave (he is not said to have been a boy, nor it to have contained snow) is not likely to have been a wanderer from the Jordan valley into the mountains of Judæa, for lions at one time were far from rare in Palestine, or even in Greece, while in prehistoric days they were common in Britain, when the climate was much colder than now.

The slopes of Pisgah, where Lot is said to have sought refuge in a cave, though they command a view of the Dead Sea, can scarcely have been subject to "volcanic storms of bitumen," which, by the way, is not usually an eruptive product. Whether it is "some thirty thousand years" since the last glacial period in Palestine may or may not be correct, but that was not indicated by the "earth's appearance above the sea," nor was the former unfit for men to live upon until "some five or six thousand years ago." "Sandstone, limestone and chalk," should probably be read "and shale," for chalk, in the strict sense of the word, is not found in Palestine. To say that the Jordan valley is not due to a "rift cut down into the rock by a flowing stream," but "to the original folding of the earth's crust," is both vague and inaccurate, and the peculiar physical features of the Kishon valley, which indirectly have so often made it a battlefield of nations, hardly receive even a passing notice. No doubt "geologically Palestine is a most interesting country with which to become acquainted," but we fear that this book will not do much to bring about so desirable a result.

OUR BOOKSHELF.

The Science of Mechanics: a Critical and Historical Account of its Development. By Prof. E. Mach. Supplement to the third English edition containing the author's additions to the seventh German edition. Translated and annotated by P. E. B. Jourdain. Pp. xiv+106. (Chicago and London: The Open Court Publishing Co., 1915.) Price 2*s.* 6*d.* net.

MACH completed the first edition of "The Science of Mechanics" at Prague in 1883. An English translation (by McCormack) appeared just ten years later, and of this two further editions embodying the alterations made in the successive German editions have been published.

With the seventh German edition (Leipzig, 1912), however, the alterations made were much more numerous and important; and the present volume, which forms a supplement to the third English edition (1907), contains a full account of them, together with some pages of notes due to the translator. It is remarkable that notwithstanding the thirty years which separate the first and seventh editions, Prof. Mach finds himself able to strike identically the same note in his new "conclusion" as he had done in the preface to the first edition. In that preface he undertook that "Mechanics will here be treated, not as a branch of mathematics, but as one of the physical sciences"; whilst in a concluding passage in the present volume he points out that "the doctrines of mechanics have developed out of the collected experiences of handicraft by an intellectual process of refinement . . . we see that the savage discoveries of bow and arrows, of the sling, and of the javelin, set up the most important law of modern dynamics—the law of inertia—long before it was misunderstood with thoroughgoing perversity by Aristotle and his learned commentators."

Mach speculates much as to the validity of the conceptions of absolute space and time, and on the effect of using as a reference system the "fixed" stars. What would have been the consequence had there existed a sufficiency of cosmic dust to render the stars invisible to an observer on the earth? In Mach's opinion the "surroundings in which we live, with their almost constant angles of direction to the fixed stars, appear to me to be an extremely special case, and I would not dare to conclude from this case to a very different one."

It is to be hoped that no library which possesses the third English edition will be without this companion volume.

Report on the Building and Ornamental Stones of Canada. Vol. ii., Maritime Provinces. By Dr. Wm. A. Parks. Pp. xii+264. Plates i–xlv, sketch maps 1–9. (Ottawa: Government Printing Bureau, 1914.)

THIS volume constitutes the third part of the monograph on the building and ornamental stones of Canada, and worthily upholds the high standard established in the earlier portion of the work. The greater part of this report is occupied by a systematic account of the quarries of the maritime provinces and of their products. The stones are considered according to the class to which they belong, *e.g.*, granite, black granite (greenstones), sandstone, limestone, &c., and arranged according to more or less definite geographical areas into which the quarries naturally fall. In order to give prominence to the economic and commercial aspect of the work, the quarries are described under the name of the owner wherever possible. The general plan adopted for the description of individual properties is: (*a*) quarry observations; (*b*) description of the stone, with tests; (*c*) economic remarks and statistics; (*d*) examples of the use of the stone. Sketch maps are given showing the geology and location of quarries in important districts; special mention must be made of the excellent colour-photo plates which show in an admirable manner the colour and appearance of the stones, a feature which should be appreciated by architects.

The Canadian Department of Mines is to be congratulated on the wisdom of undertaking a comprehensive and businesslike statement of the country's quarry resources, and not least, for carrying out a series of systematic tests on the quarry products. Whatever opinion may be held as to the value of such tests, there can be no doubt that when they are made under uniform conditions, and as nearly as possible at one time, their utility is enormously increased. The existence of this monograph should result in a great saving of time, energy, and money on the part of all users of stone in the Dominion.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Probable Error of the Amplitudes in a Fourier Series obtained from a Given Set of Observations.

MR. DINES's question (NATURE, August 12, p. 644) as to the degree of significance to be attached to the amplitudes of waves of given period found in short series of observations and the likelihood of their permanence as the series is extended brings home again the reflection that whilst probable errors are easily found where the experience is large and they are least wanted, their determination from a limited experience where they would be most useful is largely hypothetical.

One of the principal sources of error springs from the process of selection. For example, we may find by counting that twelve persons out of twenty in an omnibus, picking up people at random, are males; but to predict from this the probable constitutions in like respect of other omnibuses, or to say that the percentage of males in London has been determined as sixty, with a probable error of 7·5, is clearly a misuse of statistical theory. The result is fallacious, because of the false premises. Omnibuses do not pick up people at random, or even travelling people at random. Persons go about in small groups, and there are larger groups going to the shopping centres and going citywards, and still larger groups travelling at the extreme hours and travelling at the mid hours of the day, and so on. The constitutions of the groups are different, and the probable error of the percentage is much in excess of that calculated on the basis of random sampling, this being due to a process which, applied to phenomena in general, may be called a tendency to cluster.

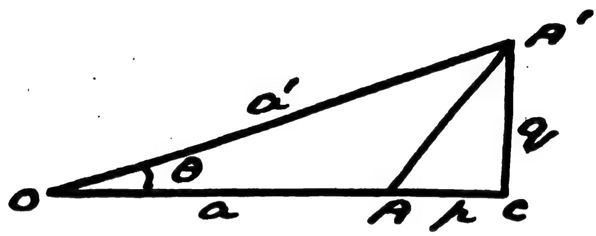
In all cases where a space or time content is taken as the sample it is necessary, owing to unknown clustering, to repeat the samples many times over, before a just estimate of the statistical constants and of their probable errors can be obtained.

Applied to meteorological and such-like phenomena, in which some value fluctuates in time, the successive observations are seldom at such a distance as to be haphazard, and the clustering, in this instance, is of the nature of waves similar to the waves which are the subject of observation. In these circumstances it does not seem possible, from observations of a single period, to make any estimate of the significance of an observed amplitude. This can only be done by repeating the period and noting the fluctuations in phase and amplitude found in such repetitions. If observations for many periods are to hand, then it is only following a well-understood practice to divide the material up into groups and calculate the constants of each group. From the fluctuations found in the several groups an empirical gauge of error may be constructed, upon which may be based a measure of error, suitable for application to the constant found for the whole.

If the phenomenon were one fully observed, and a frequency distribution of wave period and amplitude had been calculated by one of the several methods that have been proposed, then it would not be difficult to obtain the probability of error of any sustained wave found in the observations during a limited period of time. But such a frequency distribution is seldom a subject of research, although it is the first step in a description of the phenomenon, and one that cannot fail, by giving the salient periods, to mark out regions of investigation relative to the causes of undulation.

The more limited statement of the problem, as enunciated by Mr. Dines, renders it amenable to algebraical expression in the following manner.

A variable quantity has a periodic wave of amplitude a, and is subject, in addition, to casual fluctuations the mean of which is zero, and standard deviation σ. It is easily shown that if p and q are the amplitudes of the waves, phasal with, and in quadrature with, the above wave, calculated from the casual variations alone, the mean values of p and q are zero, and their standard deviations are $\sigma\sqrt{2}/\sqrt{n}$. Supposing that the distributions of p and q are normal, what will be the errors of the calculated amplitudes, and phase angles, due to these fluctuations?



Draw OA$=a$, AC$=p$, CA' at right angles$=q$.

Then, clearly, $a'=$OA' is the calculated amplitude due to p and q, superimposed upon a, and $\theta=$AOA' is the phase displacement.

Now A' has varying positions, due to the variations of p and q, and its frequency upon the element of area, dp, dq, about A', is that of a normal distribution, viz.:—

$$\frac{1}{\sqrt{(2\pi)}s} e^{-\frac{1}{2}p^2/s^2} dp \cdot \frac{1}{\sqrt{(2\pi)}s} e^{-\frac{1}{2}q^2/s^2} dq$$
$$= \frac{1}{2\pi s^2} e^{-\frac{1}{2}(p^2+q^2)/s^2} dp\, dq$$

where s is written for $\sigma\sqrt{2}/\sqrt{n}$, the *s.d.* of p or q.

Putting $p^2+q^2=\mathrm{AA'}^2=a'^2-2a'a\cos\theta+a^2$, and $dpdq=a'da'd\theta$, the variables are changed from p, q to a',θ, and the frequency distribution of a',θ *is* therefore

$$\int_0^\infty\int_0^{2\pi} \frac{1}{2\pi s^2} e^{-\frac{1}{2}(a'^2-2a'a\cos\theta+a^2)/s^2}\, a'da'd\theta.$$

When this is integrated with respect to θ the result will be the frequency distribution of amplitudes a'. It appears to be a problem of the nature of random migration, and the solution of the above integral will probably be found (I am unable to consult my reference) in Prof. Karl Pearson's memoir upon this subject.

If there is no initial wave, so that the calculated amplitudes are all due to casual fluctuations, then $a=0$ and the frequency distribution of a' becomes:—

$$\int_0^\infty \frac{1}{s^2} e^{-\frac{1}{2}a'^2/s^2}\, a'da'.$$

This is a well-known distribution, being, for instance, the distribution of arithmetical velocity of wind when the NS and EW components vary independently, in normal manner, with *s.d.* equal to s.

The mean is $\sqrt{(\frac{1}{2}\pi)}.s=1{\cdot}253s$, the standard deviation is $\sqrt{(2-\frac{1}{2}\pi)}.s=0{\cdot}655s$, and the number per cent. exceeding xs is $100\times e^{-\frac{1}{2}x^2}$.

Applying these formulæ to Mr. Dines's experimental data, the comparison of experiment with theory comes out as follows:—

Values of $a'=\surd(p^2+q^2)$. Mean p=mean q=0. *S.d.* of p=*s.d.* of q=10. 500 pairs taken.

	Experiment	Theory
Mean a'	12·5	12·53±0·20
Standard deviation of a' ...	6·5	6·55±0·14
Per cent. exceeding 25 ...	4·0	4·39±0·62

the agreement being very close in all three values.

Manchester. H. E. SOPER.

Antarctic Fossil Plants.

IT should have been stated that Prof. Seward's memoir (reviewed in NATURE for August 26) is the first dealing with the *geological* results of Capt. Scott's Expedition. Two numbers of the Zoological series had previously appeared—No. 1 of vol. i. on June 27, and No. 1 of vol. ii. on July 25, 1914.

D. H. S.

HENRY GWYN JEFFREYS MOSELEY.

SCIENTIFIC men of this country have viewed with mingled feelings of pride and apprehension the enlistment in the new armies of so many of our most promising young men of science —with pride for their ready and ungrudging response to their country's call, and with apprehension of irreparable losses to science. These forebodings have been only too promptly realised by the death in action at the Dardanelles, on August 10, of Henry Gwyn Jeffreys Moseley, 2nd Lieut. in the Royal Engineers, at the age of twenty-seven. A son of the distinguished zoologist, the late Prof. H. N. Moseley, of Oxford, he was educated at Eton, entering as a scholar, and passed to Trinity College, Oxford, where he gained a Millard Scholarship. He obtained a First Class in Mathematical Moderations, and Honours in Natural Science.

Moseley early showed marked originality and an enthusiatic interest in science. A year before his graduation he had decided to undertake original work in physics, and visited Manchester to discuss the matter with me. After graduation, he was appointed lecturer and demonstrator in the physics department of the University of Manchester, and immediately devoted all his spare time to investigation. After two years he resigned his lectureship in order to devote his energies entirely to research, and was awarded the John Harling Fellowship. During the past year he went to Oxford to live with his mother, and to continue his experiments in the laboratory of Prof. Townsend. He went out to Australia with the British Association, took an active part in the discussion on the "Structure of the Atom" at Melbourne, and gave an interesting account of his recent work on the X-ray spectra of the rare earths, in Sydney. On the outbreak of war he put aside all thought of continuing the investigations in which he was so vitally interested, and returned at once to England to offer his services to his country, and was granted a Commission in the Royal Engineers. He was later made signalling officer to the 38th Brigade of the First Army, and left for the Dardanelles on June 13. He took part in the severe fighting at the new landing on August 6 and 8, and was instantaneously killed on the 10th by a bullet through the head in the act of telephoning an order to his division at a moment when the Turks were attacking on the flank only 200 yards away.

Moseley was one of those rare examples of a man who was a born investigator. He rapidly acquired the technique of experiment and soon gained a remarkably wide and accurate knowledge of modern physics. His undoubted originality and marked capacity as an investigator were very soon ungrudgingly recognised by his co-workers in the laboratory, while his cheerfulness and willingness to help in all possible ways endeared him to all his colleagues. His first research, published in the Proceedings of the Royal Society, consisted in the determination of the average number of beta particles emitted during the transformation of an atom of radium B and radium C—a difficult and important piece of work. It then occurred to him to determine the potential to which radium could be charged in a high vacuum by the escape of its own beta particles. He was able to achieve such a high stage of exhaustion—and this before the advent of the molecular pump—that a small quantity of radioactive matter retained itself at a potential of more than 100,000 volts for several weeks. He devised an ingenious method for detecting the possible presence of very short-lived radioactive substances, and in conjunction with Fajans utilised the method to determine the period of transformation of a newly-discovered product in actinium, which was found to be half transformed in 1/500 of a second.

Moseley's interest was greatly aroused by the discovery of Laue of the diffraction of X-rays in their passage through crystals, and in conjunction with Mr. Charles Darwin he immediately started an investigation to examine the quantity and quality of the X-radiation scattered from crystals at different angles. Prof. Bragg, who was working simultaneously at Leeds on the same problem, observed the presence of definite maxima in the scattered radiation corresponding to definite lines in the X-ray spectrum. This result was confirmed and extended by Moseley and Darwin, and they mapped out accurately for the first time the spectrum of the characteristic X-radiation from an X-ray tube with a platinum antikathode. These pioneer investigations in Leeds and Manchester were of fundamental importance, for they laid the foundation of the new science of X-ray spectroscopy, which is now in the process of rapid development.

Moseley next decided to examine the X-ray spectra of a large number of different elements with the definite object of testing whether the spectrum was connected in a simple way with the atomic number of the element when arranged in increasing order of atomic weight. Suggestions had been previously made that the charge on the nucleus of an atom, which defines its chemical and physical properties, was possibly equal to the atomic number. For this purpose he developed the photographic method for accurate measure-

ments of the spectra. In his first paper he examined the spectra of a group of elements of atomic weight between calcium and zinc. He showed that a similar spectrum consisting of two strong lines was emitted by each of these elements, and proved that the frequency of the corresponding lines in the spectra was proportional to the square of a whole number which varied by unity in passing from one element to the next. This number, which was closely connected with the atomic number of the element, was considered to represent the nucleus charge. He next proceeded to make a systematic study of a great majority of the solid elements, and showed that a similar result held for them all. Since the frequency of a given line in the spectrum varied by definite jumps in passing from one element to the next, he was able to draw the deduction that there could only exist three unknown elements from aluminium to gold, and he was able to predict the atomic number and spectra of these missing elements. This new and powerful method of attack was of especial importance in connection with the much debated question of the number of the rare earth elements.

The fundamental importance of these discoveries was immediately recognised. Prof. Urbain came from Paris to Oxford in order to utilise Moseley's new method to decide the nature of the elements present in the numerous preparations he had made of the rare earths. The results of the investigation of the rare earths have not been published, but it is to be hoped that sufficient data will be available later.

Moseley's fame securely rests on this fine series of investigations, and his remarkable record of four brief years' investigation led those who knew him best to prophesy for him a brilliant scientific career. There can be no doubt that his proof that the properties of an element are defined by its atomic number is a discovery of great and far-reaching importance, both on the theoretical and the experimental side, and is likely to stand out as one of the great landmarks in the growth of our knowledge of the constitution of atoms.

It is a national tragedy that our military organisation at the start was so inelastic as to be unable, with few exceptions, to utilise the offers of services of our scientific men except as combatants in the firing line. Our regret for the untimely end of Moseley is all the more poignant that we cannot but recognise that his services would have been far more useful to his country in one of the numerous fields of scientific inquiry rendered necessary by the war than by exposure to the chances of a Turkish bullet.

E. RUTHERFORD.

THE BRITISH ASSOCIATION AT MANCHESTER.

WRITING on the eve of the British Association week, it may be said that the prospects of a good number of members and associates are much brighter now than they were a few weeks ago. The experiment of shortening the meeting and of cutting out of the programme the long-distance excursions was one that threatened to reduce the numbers considerably, but we can be assured now that a very large proportion of those who attend the meeting of the British Association are primarily attracted by the scientific programme.

The interest taken in the meeting by the citizens of Manchester and the surrounding district has very noticeably increased during the past week, and a large number of students and teachers are enrolling themselves as associates on the half-fee terms that were offered by the Council for this meeting.

The discussions that will probably attract the largest attendances from among the local members are those on industrial harmony in Section F and on military education in Section L. Mr. Balls's lecture on the application of science to the cotton industry in Section K will also attract a good audience of local people.

In addition to the afternoon sectional excursions already announced, the agriculturists have arranged visits to the Agricultural Institution of the Cheshire County Council at Holmes Chapel and to another large farm in the district.

The arrangements made by the local executive committee for the reception of the Association have now been completed, and it will be found that ample accommodation has been provided for the comfort and convenience of the visitors. In time of war there are some subjects that cannot be discussed advisedly in open section, particularly in the sections of the physical sciences; but it may be anticipated that some important work will be done in the private discussions of smaller groups of scientific men in the smoking and conversation rooms. The university and the high school for girls will between them provide facilities for such informal discussions on a larger scale, probably, than in any previous meeting of the Association.

INAUGURAL ADDRESS BY PROF. ARTHUR SCHUSTER, D.Sc., Sc.D., LL.D., DR.-ÈS-SC., F.R.S., PRESIDENT.

The Common Aims of Science and Humanity.

UNDER the influence of the diversity of pursuits imposed upon us by the conditions of modern life, different groups of the community—men of business, men of science, philosophers, or artists—have acquired detached and sometimes opposing interests. Each group, impressed by the importance of its own domain in the life of the nation, and focussing its vision on small differences and temporary rivalries, was in danger of losing the sense of mutual dependence. But in the shadow of a great catastrophe it has been brought home to us that the clash of interests is superficial, and the slender thread of union which remained has grown into a solid bond. What is the fibre from which the bond is twined? Patriotism may express its outward manifestation, but its staple is the mental relationship which remains continuous and dominant even in normal times, when each of us may peacefully go to earn his living and enjoy the course of his intellectual life.

Outwardly the community is divided into heterogeneous elements with mental attitudes cast in different moulds, and proceeding along separate roads

by differing methods to different ideals. Yet as we eliminate the superficial, and regard only the deep-seated emotions which control our thoughts and actions, the differences vanish, and the unity of purpose and sentiment emerges more and more strongly. Mind and character, no doubt, group themselves into a number of types, but the cleavage runs across, and not along, the separating line of professions.

Were it otherwise, the British Association could not perform one of its most important functions—a function not, indeed, originally contemplated, but resulting indirectly from the wise and democratic provisions in its constitution, which enabled it to adapt itself to the changing needs of the time. Our founders primarily considered the interests of scientific men; their outlook was restricted and exclusive, both as regards range of subject and membership. In the words of Sir David Brewster, who gave the first impulse to its formation, it was to be "an association of our nobility, clergy, gentry, and philosophers."

The meetings were intended to promote personal intercourse, to organise research, to advocate reform of the laws hindering research, and to improve the status of scientific men. The right of membership was confined to those who already belonged to some learned society, and William Whewell, one of the principal supporters of the movement, even suggested that only authors of memoirs published by a learned society should be admitted.[1] He emphasised this proposal by the recommendation[2] "in some way to avoid the crowd of lay members whose names stand on the List of the Royal Society." The reform of the Patent Laws and the introduction of an International Copyright were suggested as subjects suitable for discussion, not apparently from the point of view of general advantage, but merely in the interests of one section of the community.

Whatever the objects of the founders of the association may have been, it is obvious that questions of public importance could not be permanently excluded from meetings the success of which depended on the interest stimulated in the community. The Statistical Section, which owed its origin to the visit, at the first Oxford meeting (1836), of Quetelet, the Belgian astronomer and economist, was the first to assert itself by engaging in a discussion of the Poor Laws. Whewell deeply resented this violation of academic neutrality: "it was impossible," he wrote, "to listen to the Proceedings of the Statistical Section on Friday without perceiving that they involved exactly what it was most necessary and most desired to exclude from our Proceedings,"[3] and again: "Who would propose (I put it to Chalmers, and he allowed the proposal to be intolerable) an ambulatory body, composed partly of men of reputation and partly of a miscellaneous crowd, to go round year by year from town to town and at each place to discuss the most inflammatory and agitating questions of the day?"[4]

Fortunately for our association, this narrow-minded attitude did not prevail, and our records show that while not avoiding controversial and even inflammatory subjects, we have been able to exercise a powerful influence on the progress of science. The establishment of electric units, universally accepted throughout the world, originated in the work of one of our committees; the efforts which led to the foundation of the National Physical Laboratory, one of the most efficient and beneficial organisations in the country, received its first impulses from us; and the organisation of the first world service for the systematic investigation of earth tremors was established by the late Dr. Milne, working through one of our committees.

The success of these enterprises alone is sufficient to show that we are not merely a body promoting social intercourse between men of science and the rest of the community. Nevertheless, it may be admitted that our efforts have been spasmodic, and the time has arrived to consider whether it may be possible to secure not only a greater continuity in our work but also its better co-ordination with that of other scientific organisations. The present juncture affords the opportunity, and the changed conditions, which in the near future will affect all our institutions, render it indeed incumbent upon us once more to adapt ourselves to the needs of the times. Proposals for a move in that direction have already been made, and will no doubt be carefully considered by the council. In the meantime, I may direct your attention to the important discussions arranged for by our Economic Section, which alone will justify the decision of the council not to suspend the meeting this year.

It must not be supposed that, even in the early days of the association, Whewell's ideas of its functions were universally accepted. It is pleasant to contrast the lamentations of the omniscient professor of mineralogy with the weightier opinion of the distinguished mathematician who then held Newton's chair at Cambridge. At the concluding session of the second meeting of the association, Babbage expressed the hope "that in the selection of the places at which the annual meetings were to be held, attention should be paid to the object of bringing theoretical science in contact with the practical knowledge on which the wealth of the country depends." "I was myself," he said, "particularly anxious for this, owing as I do a debt of gratitude for the valuable information which I have received in many of the manufacturing districts, where I have learned to appreciate still more highly than before the value of those speculative pursuits which we follow in our academical labours. I was one of those who thought at first that we ought to adjourn for our next meeting to some larger manufacturing town; but I am now satisfied that the arrangement which has been made will be best adapted to the present state of the association. When, however, it shall be completely consolidated I trust we may be enabled to cultivate with the commercial interests of the country that close acquaintance which I am confident will be highly advantgeous to our more abstract pursuits."

Since then, as we all know, our most successful meetings have been held in manufacturing centres; but it should be observed that, while Babbage laid stress on the benefit which would accrue to pure science by being brought into contact with practical life, scientific men of the present day have more and more insisted on the services they, on their part, are able to render to the industries. The idealistic motive has thus given way to the materialistic purpose. Both aspects are perhaps equally important, but it is necessary to insist, at the present time, that the utilitarian drum can be beaten too loudly. There is more than one point of contact between different activities of the human mind, such as find expression in scientific pursuits or commercial enterprises, and it is wrong to base the advantages to be derived from their mutual influence solely, or even mainly, on the ground of material benefits.

I need not press this point in a city which has given many proofs that a business community may be prompted by higher motives than those which affect their pockets. It was not for utilitarian objects that

[1] Others were allowed to join on recommendation by the General Committee. It was only in 1906 that this restriction, which had become obsolete, was removed.

[3] *Loc. cit.*, p. 289.

[4] It is much to be desired that the documents relating to the early history of the British Association should be published in a collected form.

repeated efforts were made since the year 1640 to establish a University in Manchester; it was not for reasons of material gain that the Royal Institution and Owens College were founded; nor was it because they increased the wealth of the district that the place of honour in our Town Hall has been given to Dalton and Joule.

When we glance at the various occupations of the working parts of a nation, comprising the student who accumulates or extends knowledge, the engineer who applies that knowledge, the geologist or agriculturist who discloses the store of wealth hidden in the soil, the commercial man who distributes that wealth, it seems as if we ought to be able to name the qualities of intellect and temperament which in each pursuit are most needed to carry out the work successfully. But on trying to define these qualities we soon discover the formidable nature of the task. Reasoning power, inventive power, and sound balance of judgment are essential attributes in all cases, and the problem is reduced to the question whether there are different varieties of the attributes which can be assigned to the different occupations.

Among all subjects mathematics is perhaps the one that appears most definitely to require a special and uncommon faculty. Yet, Poincaré—himself one of the clearest thinkers and most brilliant exponents of the subject—almost failed when he attempted to fix the distinguishing intellectual quality of the mathematician. Starting from the incontrovertible proposition that there is only one kind of correct reasoning, which is logical reasoning, he raises the question why it is that everybody who is capable of reasoning correctly is not also a mathematician, and he is led to the conclusion that the characterising feature is a peculiar type of memory. It is not a better memory, for some mathematicians are very forgetful, and many of them cannot add a column of figures correctly; but it is a memory which fixes the order in which the successive steps of reasoning follow each other without necessarily retaining the details of the individual steps. This Poincaré illustrates by contrasting the memory of a chess-player with that of a mathematician. "When I play chess," he says, "I reason out correctly that if I were to make a certain move, I should expose myself to a certain danger. I should, therefore, consider a number of other moves, and, after rejecting each of them in turn, I should end by making the one which I first contemplated and dismissed, having forgotten in the meantime the ground on which I had abandoned it." "Why, then," he continues, "does my memory not fail me in a difficult mathematical reasoning in which the majority of chess-players would be entirely lost? It is because a mathematical demonstration is not a juxtaposition of syllogisms, but consists of syllogisms placed in a certain order; and the order in which its elements are placed is much more important than the elements themselves. If I have this intuition—so to speak—of the order, so as to perceive at one glance the whole of the reasoning, I need not fear to forget its elements: each of these will take its right place of its own accord without making any call on my memory."[5]

Poincaré next discusses the nature of the intellectual gift distinguishing those who can enrich knowledge with new and fertile ideas of discovery. Mathematical invention, according to him, does not consist in forming new combinations of known mathematical entities, because the number of combinations one could form are infinite, and most of them would possess no interest whatever. Inventing consists, on the contrary, in excluding useless combinations, and therefore:—"To invent is to select—to choose. . . . The expression 'choose' perhaps requires qualifying, because it recalls a buyer to whom one offers a large number of samples which he examines before making his choice. In our case the samples would be so numerous that a lifetime would not suffice to complete the examination. That is not the way things are done. The sterile combinations never present themselves to the mind of the inventor, and even those which momentarily enter his consciousness, only to be rejected, partake something of the character of useful combinations. The inventor is therefore to be compared with an examiner who has only to deal with candidates who have already passed a previous test of competence."

All those who have attempted to add something to knowledge must recognise that there is a profound truth in these remarks. New ideas may float across our consciousness, but, selecting the wrong ones for more detailed study, we waste our time fruitlessly. We are bewildered by the multitude of roads which open out before us, and, like Poincaré when he tries to play chess, lose the game because we make the wrong move. Do we not all remember how, after the announcement of a new fact or generalisation, there are always many who claim to have had, and perhaps vaguely expressed, the same idea? They put it down to bad luck that they have not pursued it, but they have failed precisely in what, according to Poincaré, is the essence of inventive power. It may be bad luck not to have had a good idea, but to have had it and failed to appreciate its importance is downright incapacity.

An objection may be raised that before a selection can be made the ideas themselves must appear, and that, even should they arrive in sufficient numbers, the right one may not be among them. It may even be argued that Poincaré gives his case away by saying that "the sterile combinations do not even present themselves to the mind of the inventor," expressing in a negative form what may be the essence of the matter. Moreover, a fertile mind like that of Poincaré would be apt to place too low a value on his own exceptional gifts. Nevertheless, if Poincaré's more detailed exposition be read attentively, and more especially the description of how the discoveries which made him famous among mathematicians originated in his mind, it will be found that his judgment is well considered and should not be lightly set aside. New ideas seldom are born out of nothing. They most frequently are based on analogies, or the recollection of a sequence of thoughts suggested by a different branch of the subject, or perhaps by a different subject altogether. It is here that the memory comes in, which is not a memory of detail, but a memory of premises with their conclusions, detached from the particular case to which they were originally applied. Before we pronounce an adverse opinion on Poincaré's judgment, we must investigate what constitutes novelty in a new idea; but the subject is too vast to be dealt with here, nor can I attempt to discuss whether an essential distinction exists between mathematical invention and that more practical form of invention with which, for instance, the engineer has to deal.

If Poincaré, by this introspective analysis of his own powers, has dimmed the aureole which, in the eyes of the public, surrounds the mathematician's head, he removes it altogether by his definition of mathematics. According to him, "mathematics is the art of calling two different things by the same name." It would take me too far were I to try to explain the deep truth expressed in this apparently flippant form: physicists, at any rate, will remember the revolution created in the fundamental outlook of science by the application of the term "energy" to

[5] "Science et Méthode," pp. 46 and 47.

the two quite distinct conceptions involved in its subdivisions into potential and kinetic energy.

Enough has been said to show that the peculiar powers necessary for the study of one of the most abstruse branches of knowledge may be expressed in terms which bring them down to the level at which comparison with other subjects is possible. Applying the same reasoning to other occupations, the same conclusion is inevitable. The commercial man, the politician, and the artist must all possess the type of memory best suited to concentrate in the field of mental vision their own experiences as well as what they have learned from the experience of others; and, further, they must have the power of selecting out of a multitude of possible lines of action the one that leads to success; it is this power which Poincaré calls the inventive faculty.

The argument must not be pushed too far, as it would be absurd to affirm that all differences in the capability of dealing successfully with the peculiar problems that occur in the various professions may be reduced to peculiarities of memory. I do not even wish to assert that Poincaré's conclusions should be accepted without qualification in the special case discussed by him. What is essential, to my mind, is to treat the question seriously, and to dismiss the vague generalities which, by drawing an artificial barrier between different groups of professions, try to cure real or imaginary defects through plausible though quite illusory remedies. All these recommendations are based on the fallacy that special gifts are associated with different occupations. Sometimes we are recommended to hand over the affairs of the nation to men of business; sometimes we are told that salvation can only be found in scientific methods—what is a man of business, and what is a scientific method? If you define a man of business to be one capable of managing large and complicated transactions, the inference becomes self-evident; but if it be asserted that only the specialised training in commercial transactions can develop the requisite faculties, the only proof of the claim that could be valid would be the one that would show that the great majority of successful statesmen, or political leaders, owed their success to their commercial experience. On the other hand, every method that leads to a correct result must be called a scientific method, and what requires substantiating is that scientific training is better than other training for discovering the correct method. This proof, as well as the other, has not been, and, I think, cannot be, given. When, therefore, one man calls for the conduct of affairs "on business lines" and the other clamours for scientific methods, they either want the same thing or they talk nonsense. The weak point of these assertions contrasting different classes of human efforts is that each class selects its own strongest men for comparison with the weakest on the other side. Where technical knowledge is required, the specialist should be consulted, but in questions of general policy he is seldom the best judge.

The most fatal distinction that can be made is the one which brings men of theory into opposition to men of practice, without regard to the obvious truth that nothing of value is ever done which does not involve both theory and practice; while theory is sometimes overbearing and irritating, there are among those who jeer at it some to whom Disraeli's definition applies: the practical man is the man who practises the errors of his forefathers. With refined cruelty Nemesis infects us with the disease most nearly akin to that which it pleases us to detect in others. It is the most dogmatic of dogmatics who tirades against dogma, and only the most hopeless of theorists can declare that a thing may be right in theory and wrong in practice.

Why does a theory ever fail, though it may be sound in reasoning? It can only do so because every problem involves a much larger number of conditions than those which the investigator can take into account. He therefore rejects those which he believes to be unessential, and if his judgment is at fault he goes wrong. But the practical man will often fail for the same reason. When not supported by theoretical knowledge he generalises the result of an observation or experiment, applying it to cases where the result is determined by an altogether different set of conditions. To be infallible the theorist would have to take account of an infinite number of circumstances, and his calculations would become unmanageable, while the experimenter would have to perform an infinite number of experiments, and both would only be able to draw correct conclusions after an infinite lapse of time. They have to trust their intuition in selecting what can be omitted with impunity, and, if they fail, it is mainly due to the same defect of judgment. And so it is in all professions: failure results from the omission of essential considerations which change the venue of the problem.

Though theory and practice can only come into opposition when one of them is at fault, there is undoubtedly a contrast in character and temperament between those who incline more towards the one and those who prefer the other aspect; some like a solitary life at the desk, while others enjoy being brought into contact with their fellows. There have at all times been men predestined by nature to be leaders, and leadership is required in all branches of knowledge—the theoretical as well as the more active pursuits; but we must guard against accepting a man's estimate of his own power to convert his thoughts into acts. In the ordinary affairs of life a man who calls himself a man of action is frequently only one who cannot give any reasons for his actions. To claim that title justly a man must act deliberately, have confidence in his own judgment, sufficient tenacity of purpose to carry it through, and sufficient courage to run the unavoidable risks of possible failure. These risks may be trivial or they may be all-important. They may affect the reputation of one unit of creation or involve the whole life of a nation, and according to the greatness of the issue we shall honour the man who, having taken the risk, succeeds. But whether the scale be microscopic or interstellar, the essence of the faculty of blending theory and practice is the same, and both men of books and men of action are to be found in the philosopher's study and the laboratory, as well as in the workshop or on the battlefield. Modern science began, not at the date of this or that discovery, but on the day that Galileo decided to publish his Dialogues in the language of his nation. This was a deliberate act destined to change the whole aspect of science which, ceasing to be the occupation of a privileged class, became the property of the community. Can you, therefore, deny the claim of being a man of action to Galileo, can you deny it to Pasteur, Kelvin, Lister, and a host of others? There are, no doubt, philosophers who cannot manage even their own affairs, and whom it would be correct to call pure theorists, but that proves nothing, because their defect makes them worse philosophers as well as worse citizens.

In his presidential address, delivered to this Association in 1899, Sir Michael Foster summarised the essential features of the scientific mind. Above all other things he considered that its nature should be such as to vibrate in unison with what it is in search of; further, it must possess alertness, and

finally moral courage. Yet after enumerating these qualities, he arrives at the same result which I have tried to place before you, that there are no special peculiarities inherent in the scientific mind, and he expresses this conclusion in the following words:—

"But, I hear someone say, these qualities are not the peculiar attributes of the man of science, they may be recognised as belonging to almost everyone who has commanded or deserved success, whatever may have been his walk in life. That is so. That is exactly what I would desire to insist, that the men of science have no peculiar virtues, no special powers. They are ordinary men, their characters are common, even commonplace. Science, as Huxley said, is organised common-sense, and men of science are common men drilled in the ways of common-sense."

This saying of Huxley's has been repeated so often that one almost wishes it were true, but unfortunately I cannot find a definition of common-sense that fits the phrase. Sometimes the word is used as if it were identical with *uncommon* sense, sometimes as if it were the same thing as common *nonsense*. Often it means untrained intelligence, and in its best aspect it is, I think, that faculty which recognises that the obvious solution of a problem is frequently the right one. When, for instance, I see, during a total solar eclipse, red flames shooting out from the edge of the sun, the obvious explanation is that these are real phenomena caused by masses of glowing vapours ejected from the sun; and when a learned friend tells me that all this is an optical illusion due to anomalous refraction, I object on the ground that the explanation violates my common-sense. He replies by giving me the reasons which have led him to his conclusions, and, though I still believe that I am right, I have to meet him with a more substantial reply than an appeal to my own convictions. Against a solid argument common-sense has no power and must remain a useful but fallible guide which both leads and misleads all classes of the community alike.[6]

If we must avoid assuming special intellectual qualities when we speak of groups of men within one country, we ought to be doubly careful not to do so without good reason in comparing different nations. So-called national characteristics are in many cases matters of education and training; and, if I select one as an example, it is because it figures so largely in public discussions at the present moment. I refer to that expedient for combining individual efforts which goes by the name of organisation. An efficient organisation requires a head that directs and a body that obeys; it works mainly through discipline, which is its most essential attribute. Every institution, every factory, every business establishment is a complicated organism, and no country ever came to prominence in any walk of life unless it possessed the ability to provide for the efficient working of such organisms. To say that a nation which has acquired and maintained an empire, and which conducts a large trade in every part of the world, is deficient in organising power is therefore an absurdity. Much of the current self-depreciation in this respect is due to the confusion of what constitutes a true organisation with that modification of it which to a great extent casts aside discipline and substitutes co-operation. Though much may be accomplished by co-operation, it is full of danger in an emergency, for it can only work if it be loyally adhered to; otherwise it resembles a six-cylinder motor in which every sparking-plug is allowed to fix its own time of firing. Things go well so long as the plugs agree; but there is nearly always one among them that persists in taking an independent course and, when the machine stops, complains that the driver is inefficient. The cry for organisation, justifiable as it no doubt often is, resolves itself, therefore, into a cry for increased discipline, by which I do not mean the discipline enforced at the point of the bayonet, but that voluntarily accepted by the individual who subordinates his own convictions to the will of a properly constituted authority.

This discipline is not an inborn quality which belongs more to one nation than to another; it is acquired by education and training. In an emergency, it is essential to success, but if it be made the guiding principle of a nation's activity, it carries dangers with it which are greater than the benefits conferred by the increased facility for advance in some directions.

If there be no fundamental difference in the mental qualifications which lead to success in our different occupations, there is also none in the ideals which move us in childhood, maintain us through the difficulties of our manhood, and give us peace in old age. I am not speaking now of those ideals which may simultaneously incite a whole nation to combined action through religious fervour or ambition of power, but I am speaking of those more individual ideals which make us choose our professions and give us pleasure in the performance of our duties.

Why does a scientific man find satisfaction in studying Nature?

Let me once more quote Poincaré[7]:—

"The student does not study Nature because that study is useful, but because it gives him pleasure, and it gives him pleasure because Nature is beautiful; if it were not beautiful it would not be worth knowing and life would not be worth living. I am not speaking, be it understood, of the beauty of its outward appearance—not that I despise it, far from it, but it has nothing to do with science: I mean that more intimate beauty which depends on the harmony in the order of the component parts of Nature. This is the beauty which a pure intelligence can appreciate and which gives substance and form to the scintillating impressions that charm our senses. Without this intellectual support the beauty of the fugitive dreams inspired by sensual impressions could only be imperfect, because it would be indecisive and always vanishing. It is this intellectual and self-sufficing beauty, perhaps more than the future welfare of humanity, that impels the scientific man to condemn himself to long and tedious studies. And the same search for the sense of harmony in the world leads us to select the facts in Nature which can most suitably enhance it, just as the artist chooses among the features of his model those that make the portrait and give it character and life. There need be no fear that this instinctive and unconscious motive should tempt the man of science away from the truth, for the real world is far more beautiful than any vision of his dreams. The greatest artists that ever lived—the Greeks—constructed a heaven, yet how paltry that heaven is compared to ours! And it is because simplicity and grandeur are beautiful that we select by preference the simplest and grandest facts, and find our highest pleasure, sometimes in following the gigantic orbits of the stars, sometimes in the microscopic study of that minuteness which also is a grandeur, and sometimes in piercing the secrets of geological times which attract us because they are remote. And we see that the cult of the beautiful guides us to the same goal as the study of the useful."

[6] Since writing the above, I find on reading Prof. J. A. Thomson's "Introduction to Science" a similar criticism of Huxley's dictum. Prof. Thomson's general conclusions are not, however, in agreement with those here advocated.

[7] *Loc. cit.*, p. 15.

"Whence comes this harmony? Is it that things that appear to us as beautiful are simply those which adapt themselves best to our intelligence, and are therefore the tools which that intelligence handles most easily; or is it all the play of evolution and natural selection? In that case, those races only survived whose ideals best conformed with their interests, and while all nations pursued their ideals without regard to consequences, some were led to perdition and others achieved an empire. One is tempted to believe that such has been the course of history, and that the Greeks triumphed over the barbarians, and Europe, inheritor of Greek thought, rules the world, because the savages cared only for the sensual enjoyment of garish colours and the blatant noise of the drum, while the Greeks loved the intellectual beauty which is hidden beneath the visible beauty. It is that higher beauty which produces a clear and strong intelligence." If the mathematician's imagination is fired by the beauty and symmetry of his methods, if the moving spring of his action is identical with that of the artist, how much truer is this of the man of science who tries by well-designed experiments to reveal the hidden harmonies of Nature? Nor would it be difficult, I think, to trace the gratification inherent in the successful accomplishments of other intellectual pursuits to the same source.

Though Poincaré was, I believe, the first to lay stress on the connection between the search for the beautiful and the achievement of the useful, the æsthetic value of the study of science had previously been pointed out, and well illustrated, by Karl Pearson in his "Grammar of Science." As expressed by him: "It is this continual gratification of the æsthetic judgment which is one of the chief delights of pure science." Before we advance, however, any special claim for the pursuit of science based on these considerations, we must pause to think whether they do not equally apply to other studies or occupations. For this purpose, the nature of the æsthetic enjoyment involved must be remembered. We do not mean by it, the pleasure we feel in the mere contemplation of an impressive landscape or natural beauty, but it resembles more the enjoyment experienced on looking at a picture where, apart from the sensual pleasure we are affected by the relation between the result of the representation and that which is represented. The picture, quite apart from what it may be trying to imitate, has a certain beauty due to its contrast of colours or well-balanced arrangement. We have in one case a number of pigments covering a space of two dimensions, and in the other the natural object in three dimensions made up of entirely different materials and showing an infinite variety of detail and appearance. By itself alone either a mere photographic representation, or a geometrical arrangement of colour and line, leaves most of us cold; though both have their own particular beauty, the art consists in bringing them into connection. Bearing in mind the æsthetic value of the relationship of the work of our brain or hand to external facts or appearances, it might easily be shown that what has been said of science equally applies to other studies, such as history or literature. We may even go further, and say that any occupation whatever, from which we can derive an intellectual pleasure, must possess to a greater or smaller degree the elements of combining the useful with the beautiful.

In order to trace in detail the part played by purely emotional instincts in directing the course of our lives, we should have to study the causes which influence a child, free to select his future profession. Having eliminated secondary efforts, such as early associations, or the personal influence of an inspiring teacher, we should probably be brought to a standstill by the dearth of material at our disposal, or led into error by taking our own individual recollections as typical. Nevertheless it is only through the record of each man's experience that we may hope to arrive at a result. If every man who has reached a certain recognised position in his own subject—it need not be pre-eminence—would write down his own recollections of what led him to make the choice of his profession, we might hope to obtain facts on which a useful psychological study might be based. Scientific men as a class are not modest, but they share with other classes the reluctance to speak of their early life, owing to a certain shyness to disclose early ambitions which have not been realised. It requires courage to overcome that shyness, but I think that we need feel no shame in revealing the dreams of our childhood and holding fast to them despite the bondage of our weakness, despite the strife ending so often in defeat, despite all the obstacles which the struggle for existence has placed in our path. In some form they should persist throughout our lives and sustain us in our old age.

But the account of our early life should be simple, detached from any motives of self-depreciation or self-assertion, and free from any desire to push any particular moral or psychological theory. We want to trace the dawn of ambition, the first glimmering in the child's mind that there is something that he can do better than his fellows and reminiscences of early likes and dislikes which, though apparently disconnected from maturer tendencies, may serve as indications of a deep-seated purpose in life. It may be difficult to resist the temptation of trying to justify one's reputation in the eyes of the world; but it is worth making the effort. The only example that I know of such an autobiographical sketch is that of Darwin, which is contained in his "Life and Letters," published by his son, Sir Francis Darwin.

The ambition of a child to be better, cleverer, or more beautiful than its fellows is in the main, I think, a wish to please and to be praised. As the child grows up, the ambition becomes more definite. It is not a sordid ambition for ultimate wealth or power, nor is it an altruistic ambition to do good for the sake of doing good. Occasionally it takes the form confessed to by Darwin, when he says: "As a child I was much given to inventing deliberate falsehoods, and this was always done for the sake of causing excitement." This desire to be conspicuous was, in Darwin's case, consistent with extreme modesty, amounting almost to a want of confidence in himself, as appears in this passage: "I remember one of my sporting friends, Turner, who saw me at work with my beetles, saying that I should some day be a Fellow of the Royal Society, and this notion seemed to me to be preposterous."

We next come to the stage where a child is attracted by one subject more than another, and, if his choice be free, will select it for his life's career. What guides him in this choice? If it be said that a boy gravitates towards that subject which he finds easiest, we are led to the further question, why does he find it easiest? It is on this point that more information is required, but I am inclined to answer in accordance with Poincaré's views that it is because its particular beauty appeals most strongly to his emotional senses. In questions of this kind everyone must form his own conclusions according to his personal recollections, and these convince me that the emotional factor appears already at an early age. It is the strong attraction towards particular forms of reasoning, more perhaps even than the facility with which reasoning comes, that carries us over the initial

difficulties and the drudgery that must accompany every serious study.

I have already alluded to the different tendencies of individuals either to prefer solitary reflection or to seek companionship. Almost in every profession we find men of both types. Darwin's autobiography furnishes a good example of the man who prefers to learn through quiet reading rather than through lectures, but to many men of science the spoken word is inspiring and contact with congenial minds almost a necessity.

From our present point of view the most interesting passages in Darwin's autobiography are those indicating the æsthetic feeling which, like Poincaré, he connects with scientific research. Referring to his early studies we find this passage: "I was taught by a private tutor, and I distinctly remember the intense satisfaction which the clear geometrical proofs gave me. I remember with equal distinctness the delight which my uncle gave me by explaining the principle of the vernier of a barometer." To a man who apparently had no pronounced facility of mastering mathematical difficulties this feeling of satisfaction is especially remarkable. The combination of scientific ability with leanings either to music, or art, or poetry, is very common, and examples are to be found in almost every biography of men of science. It is difficult indeed to name an eminent scientific man who has not strong leanings towards some artistic recreation: we find the poetic vein in Maxwell and Sylvester, the musical talent in Helmholtz and Rayleigh, and the enthusiastic though amateurish pictorial efforts of less important men. That the similarities are to be found also in temperament may be noticed on reading Arnold Bennett's article on "The Artist and the Public,"[8] where many passages will be seen to be applicable to students of science as well as to writers of fiction.

If we look for distinctions between different individuals, we may find one in their leanings either towards the larger aspects of a question or the microscopic study of detail. The power of focussing simultaneously the wider view and the minute observation is perhaps the most characteristic attribute of those who reach the highest eminence in any profession, but the great majority of men have a notable predilection for the one or other side. Though it is indispensable for a scientific man to study the details of the particular problem he is trying to solve, there are many who will lose interest in it as soon as they believe they can see a clear way through the difficulties without following up their solution to its utmost limits. To them detail, as such, has no interest, and they will open and shut a door a hundred times a day without being even tempted to inquire into the inner working of the lock and latch.

There is only one feature in the operation of the intelligence by means of which a sharp division may possibly be drawn between brain-workers showing special capabilities in different subjects. In some persons thought attaches itself mainly to language, in others to visualised images, and herein lies perhaps the distinction between the literary and scientific gift. Those who, owing to external circumstances, have resided in different countries are sometimes asked in what language they think. Speaking for myself, I have always been obliged to answer that, so far as I can tell, thought is not connected with any language at all. The planning of an experiment or even the critical examination of a theory is to me entirely a matter of mental imagery, and hence the experience, which I think many scientific men must have shared, that the conversion of thought into language, which is necessary when we wish to communicate its results to others, presents not only the ordinary difficulties of translation, but reveals faults in the perfection or sequence of the images. Only when the logic of words finally coincides with the logic of images do we attain that feeling of confidence which makes us certain that our results are correct.

A more detailed examination of the instinctive predilections of a child would, I think, confirm Poincaré's conclusion that a decided preference for one subject is in the main due to an unconscious appeal to his emotions. It should be remembered, however, that the second step of Poincaré's philosophy is as important as the first. The mere emotional impulse would die out quickly, if it were not supplemented by the gratification experienced on discovering that the search for the beautiful leads us to results which satisfy our intellect as well as our emotions. There may still be bifurcations in the second portion of the road. Some may rest content with achieving something that supplies the material needs of humanity, others may be inspired to search for the deeper meaning of our existence.

There remains, therefore, some justification for the question why we persist in studying science apart from the mere intellectual pleasure it gives us. It was once a popular fallacy to assume that the laws of nature constituted an explanation of the phenomena to which they applied, and people then attached importance to the belief that we could gauge the mind of the Creator by means of the laws which govern the material world, just as we might trace the purpose of a human legislator in an Act of Parliament. As this archaic interpretation was abandoned, philosophers went, in accordance with what politicians call the swing of the pendulum, to the other extreme. We can explain nothing, they said—in fact, we can know nothing—all we can do is to record facts. This modesty was impressive and it became popular. I know, at any rate, one scientific man who has acquired a great reputation for wisdom by repeating sufficiently often that he knows nothing, and, though his judgment may be true, this frame of mind is not inspiring. As a corrective to the older visionary claims, which centred round the meaning of the word "explain," the view that the first task of science is to record facts has no doubt had a good influence. Kirchhoff laid it down definitely that the object of science is to describe nature, but he did not thereby mean that it should be confined to recording detached observations; this would be the dullest and most unscientific procedure. Description, in the sense in which Kirchhoff uses it, consists in forming a comprehensive statement gathering together what, until then, was only a disconnected jumble of facts. Thus the apparently quite irregular motions of the planets, as observed from the earth, were first collected in tabular form. This was a necessary preliminary, but was not in itself a scientific investigation. Next came Kepler, who by means of three laws summed up the facts in their main outlines, and the description then took a more refined form, substituting half a page of printing for volumes of observations. Finally, Newton succeeded in predicting the planetary movements on the assumption of a gravitational attraction between all elements of matter. According to Kirchhoff, the chief merit of this discovery would lie in its condensing Kepler's three laws into one hypothesis. This point of view is not necessarily opposed to that of Poincaré, because it is exactly the simplicity of Newton's explanation that appeals most strongly to our æsthetic sense, but there is an important difference in the manner of expression. However beautiful an idea may be, it

[8] *English Review*, October, 1913.

loses its effect by being placed before us in an unattractive form. This criticism also applies to Mach, according to whom the object of science is to economise thought, just as it is the object of a machine to economise effort. Logically, this definition is justified, and it may be the best that can be given, if we prefer using a technical expression to confessing an emotional feeling. But why should we do so? Is it not better to recognise that human intelligence is affected by sentiment as much as by reasoning? It is a mistake for scientific men to dissociate themselves from the rest of humanity, by placing their motives on a different, and, at the best, only superficially higher, level. When an adventurous spirit, for instance, desires to organise an expedition to unknown regions of the world, we try to induce our Governments to provide the necessary funds by persuading them, and incidentally ourselves, that we do so because important scientific results may be expected from the expedition. This may actually be the case, but we are mainly affected by the same motives as the rest of the community; if the truth be told, we are as curious as others to know what every corner of the earth looks like, and we join them in wishing to encourage an enterprise requiring perseverance and involving danger.

I fully realise that the wish to justify one's own work in the eyes of the world will always lead to fresh attempts to find a formula expressing the objects which we desire to attain. Enough, however, has been said to show that the definition must take account of sentiment, without insisting too much upon it. Nor can we hope, in view of the variety of intellectual and emotional pleasures which combine to create the charm of science, to include all points of view, but if I were forced to make a choice I should say that the object of science is to predict the future. The wish to know what lies before us is one of the oldest and most enduring desires of human nature; often, no doubt, it has degenerated and given rise to perverted and ignoble longings, but its accomplishment, when it can be achieved by legitimate inquiry, is a source of the purest and most satisfying enjoyment that science can give. We feel that enjoyment each time we repeat an old and perhaps hackneyed experiment. The result is known beforehand, but be it only that we expect the colour of a chemical precipitate to be green or yellow, be it only that we expect a spot of light to move to the right or left, there is always a little tremor of excitement at the critical moment, and a satisfying feeling of pleasure when our expectation has been realised. That pleasure is, I think, enhanced when the experiment is not of our own making, but takes place uncontrolled by human power. In one of Heine's little verses he makes light of the tears of a young lady who is moved by the setting sun. "Be of good cheer," the poet consoles her, "this is only the ordinary succession of events; the sun sets in the evening and rises in the morning." If Heine had been a man of science, he would have known that the lady's tears found a higher justification in the thought of the immutable and inexorable regularity of the sun's rising and setting than in the fugitive colour impression of his descent below the horizon, and that her emotions ought to be intensified rather than allayed by the thought of his resurrection in the morning—everybody's life contains a few unforgettable moments which, at quite unexpected times, will vividly rise in his mind, and there are probably some in this hall who have experienced such moments at the beginning of a total eclipse of the sun. They have probably travelled far, and gone through months of preparation, for an event which only lasts a few minutes. The time of first contact is approaching, in a few seconds the moon is about to make its first incision in the solar disc, and now the observer's thoughts come crowding together. What if there were a mistake in our calculations? What if we had chosen a spot a few miles too far north or too far south? What if the laws of gravitation were ever so little at fault? But now at the predicted time, at the calculated spot on the sun's edge, the dark moon becomes visible, and the feeling of relief experienced concentrates into one tense instant all the gratitude we owe those who have given precision to the predictions of celestial movements, leaving them expressible by a simple law which can be written down in two lines. It is this simplicity of the law of gravitation, and its accuracy, which some day may show limitations, but has hitherto withstood all tests, that gives to astronomy its pre-eminence over all sciences.

Indeed, if we classify the different sections into which science may be divided, I think it may be said that their aim, in so far as it is not purely utilitarian, is always either historic or prophetic; and to the mathematician, history is only prophecy pursued in the negative direction. It is no argument against my definition of the objects of science, that a large section of its subdivisions has been, and to some extent still is, mainly occupied with the discovery and classification of facts; because such classification can only be a first step, preparing the way for a correlation into which the element of time must enter, and which therefore ultimately must depend either on history or prophecy.

Latterly men of science, and in particular physicists, have given increased attention to the intrinsic meaning of the concepts by means of which we express the facts of nature. Everything—who can deny it?—is ultimately reduced to sense impressions, and it has therefore been asserted that science is the study of the mind rather than of the outside world, the very existence of which may be denied. The physicist has thus invaded the realm of philosophy and metaphysics, and even claims that kingdom as his own. Two effects of these efforts, a paralysing pessimism and an obscure vagueness of expression, if not of thought, seriously threatened a few years ago to retard the healthy progress of the study of nature. If the outside world were only a dream, if we never could know what really lies behind it, the incentive which has moved those whose names stand out as landmarks in science is destroyed, and it is replaced by what? By a formula which only appeals to a few spirits entirely detached from the world in which they live. Metaphysicians and physicists will continue to look upon science from different points of view, and need not resent mutual criticisms of each other's methods or conclusions. For we must remember that most of the good that is done in this world is done by meddling with other people's affairs, and though the interference is always irritating and frequently futile, it proves after all that our interests converge towards a common centre.

According to Poincaré, the pleasure which the study of science confers consists in its power of uniting the beautiful and the useful; but it would be wrong to adopt this formula as a definition of the object of science, because it applies with equal force to all human studies. I go further, and say that the combination of the search for the beautiful with the achievement of the useful is the common interest of science and humanity. Some of us may tend more in one direction, some in another, but there must always remain a feeling of imperfection and only partial satisfaction unless we can unite the two fundamental desires of human nature.

I have warned you at the beginning of this discourse

not to beat the utilitarian drum too loudly, and I have laid stress throughout on the idealistic side, though the most compelling events of the moment seem to drive us in the other direction, and the near future will press the needs of material prosperity strongly upon us. I must guard myself, therefore, against one criticism which the trend of my remarks may invite. At times, when the struggle for existence keeps masses in permanent bondage, in a society in which a multitude of men and women have to face starvation, and when unfortunate, though purely accidental, surroundings in childhood drive the weak into misery, is it not futile to speak of æsthetic motives? Am I not, while endeavouring to find a common bond between all sections of the community, in reality drawing a ring round a small and privileged leisured class, telling them these enjoyments are for you and for you alone? Should I not have found a surer ground for the claims of science in its daily increasing necessity for the success of our manufactures and commerce?

I have said nothing to indicate that I do not put the highest value on this important function of science, which finds its noblest task in surrendering the richness of its achievements to the use of humanity. But I must ask you to reflect whether the achievement of wealth and power, to the exclusion of higher aims, can lead to more than a superficial prosperity which passes away, because it carries the virus of its own doom within it. Do we not find in the worship of material success the seed of the pernicious ambition which has maddened a nation, and plunged Europe into war? Is this contempt for all idealistic purposes not the origin of the mischievous doctrine that the power to possess confers the right to possess, and that possession is desirable in itself without regard to the use which is made of it? I must therefore insist that if we delight in enlisting the wealth accumulated in the earth, and all the power stored in the orbs of heaven, or in the orbits of atomic structure, it should not be because we place material wealth above intellectual enjoyment, but rather because we experience a double pleasure if the efforts of the mind contribute to the welfare of the nation. When Joule taught us to utilise the powers at our disposal to the best advantage he did it not—and his whole life is a proof of it—to increase either his own wealth or that of the nation, but because, brought up in commercial life and deeply imbued with the deep insight and genius of science, he found his greatest delight in that very combination of æsthetic satisfaction and useful achievement which Poincaré has so well described. And again, when another of our fellow-citizens, Henry Wilde, showed how electrical power can be accumulated until it became an efficient instrument for the economic transmission of work, he found his inspiration in the intellectual gratification it gave him, rather than in the expectation of material gain. I am drawing no ring round a privileged class, but urge that the hunger for intellectual enjoyment is universal, and everybody should be given the opportunity and leisure of appeasing it. The duty to work, the right to live, and the leisure to think are the three prime necessities of our existence, and when one of them fails we only live an incomplete life.

I should have no difficulty in illustrating by examples, drawn from personal experience, the power which the revelations of science can exert over a community steeped in the petty conflicts of ordinary life; but I must bring these remarks to a conclusion, and content myself with the account of one incident.

An American friend, who possessed a powerful telescope, one night received the visit of an ardent politician. It was the time of a Presidential election, Bryan and Taft being the opposing candidates, and feeling ran high. After looking at clusters of stars and other celestial objects, and having received answers to his various questions, the visitor turned to my friend:—

"And all these stars I see," he asked, "what space in the heaven do they occupy?"

"About the area of the moon."

"And you tell me that every one of them is a sun like our own?"

"Yes."

"And that each of them may have a number of planets circulating round them like our sun?"

"Yes."

"And that there may be life on each of these planets?"

"We cannot tell that, but it is quite possible that there may be life on many of them."

And after pondering for some time, the politician rose and said: "It does not matter after all whether Taft or Bryan gets in."

Happy were the times when it could be said with truth that the strife of politics counted as nothing before the silent display of the heavens. Mightier issues are at stake to-day: for in the struggle which convulses the world, all intellectual pursuits are vitally affected, and science gladly gives all the power she wields to the service of the State. Sorrowfully she covers her face because that power, acquired through the noblest efforts of the sons of all nations, was never meant for death and destruction; gladly she helps, because a war wantonly provoked threatens civilisation, and only through victory shall we achieve a peace in which once more science can hold up her head, proud of her strength to preserve the intellectual freedom which is worth more than material prosperity, to defeat the spirit of evil that destroys the sense of brotherhood among nations, and to spread the love of truth.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS (SLIGHTLY ABRIDGED) BY SIR F. W. DYSON, M.A., LL.D., F.R.S., PRESIDENT OF THE SECTION.

ALTHOUGH at the present time our minds are largely absorbed by the war, the meeting of the British Association in Manchester indicates that we consider it right to make our annual review of scientific progress. I shall therefore make no apology for choosing the same subject for my address as I should have chosen in other circumstances. It is a subject far removed from war, being an account of the manner in which astronomers have with telescopes and spectroscopes investigated the skies and the conclusions they have reached on what Herschel called "The Construction of the Heavens."

Our knowledge of the fixed stars, as they were called by the old astronomers, is of comparatively recent origin, and is derived from two sources: (1) the measurement of small changes in the positions of the stars in the sky, and (2) the analysis of the light received from them and the measurement of its amount. To this end the numerous instruments of a modern observatory have been devised. The desire to examine fainter objects, and still more the necessity of increasing the accuracy of observations, has brought about a continuous improvement in the range and accuracy of astronomical instruments. Methods which had been perfected for observations of a few stars have been extended so that they can be applied to a large number. For these reasons the progress

of sidereal astronomy may seem to have gone on slowly for a time. The more rapid progress of recent years arises from the accumulation of data, for which we are indebted to generations of astronomers, and from the gradual increase in power and perfection of our instruments.

The first insight into the stars as a whole naturally came from the survey of their numbers and distribution; and Herschel, who constructed the first great telescopes, explored the heavens with untiring skill and energy, and speculated boldly on his observations, is justly regarded as the founder of sidereal astronomy. In his great paper "On the Construction of the Heavens," Herschel gives the rules by which he was guided, which I should like to quote, as they may well serve as a motto to all who are engaged in the observational sciences:—

"But first let me mention that if we would hope to make any progress in an investigation of this delicate nature we ought to avoid two opposite extremes of which I can hardly say which is the most dangerous. If we indulge a fanciful imagination and build worlds of our own, we must not wonder at our going wide from the path of truth and nature; but these will vanish like the Cartesian vortices, that soon gave way when better theories were offered. On the other hand, if we add observation to observation, without attempting to draw not only certain conclusions but also conjectural views from them, we offend against the very end for which only observations ought to be made. I will endeavour to keep a proper medium; but if I should deviate from that I could wish not to fall into the latter error." In this spirit he discussed the "star gauges" or counts of stars visible with his great reflector in different parts of the sky, and concluded from them that the stars form a cluster which stretches to an unknown but finite distance, considerably greater in the plane of the Milky Way than in the perpendicular direction. He gave this distance as 497 times that of Sirius. He did not hesitate to advance the theory that some of the nebulæ were similar clusters of stars, of which that in Andromeda, judging from its size, was the nearest. Herschel had no means of telling the scale of the sidereal system, though he probably supposed the parallax of Sirius to be of the order of 1″.

Though some of the assumptions made by Herschel are open to criticism, the result at which he arrived is correct in its general outline. I shall attempt to give a brief account of some of the principal methods used to obtain more definite knowledge of the extent and constitution of this "island universe." The stars of which most is known are, in general, those nearest to us. If the distance of a star has been measured, its co-ordinates, velocity perpendicular to the line of sight, and luminosity are easily found. In the case of a double star the orbit of which is known the mass may also be determined. But only a very small proportion of the stars are sufficiently near for the distance to be determinable with any accuracy. Taking the distance corresponding to a parallax of 1″ or the parsec as unit—*i.e.* 200,000 times the distance of the earth from the sun—fairly accurate determinations can be made up to a distance of 25 parsecs, but only rough ones for greater distances.

For much greater distances average results are obtainable from proper motions, and the mean distances of particular classes of stars—for instance, stars of a given magnitude or given type of spectrum—can be found with confidence up to a distance of 500 parsecs, and with considerable uncertainty to twice this distance. The density of stars in space as a function of the distance, the percentage of stars within different limits of luminosity, the general trend of the movements of stars and their average velocities can also be found, within the same limits of distance.

For all distances, provided the star is sufficiently bright, its velocity to or from the earth can be measured. The general consideration of these velocities supplies complementary data which cannot be obtained from proper motions, and confirms other results obtained by their means. For distances greater than 1000 parsecs our knowledge is generally very vague. We have to rely on what can be learned from the amount and colour of the light of the stars, and from their numbers in different parts of the sky.

Parallax.

Let us begin with the portion of space nearest to us, within which the parallaxes of stars are determinable. The successful determination of stellar parallax by Bessel, Struve, and Henderson in 1838 was a landmark in sidereal astronomy. The distances of three separate stars were successfully measured, and for the first time the sounding line which astronomers had for centuries been throwing into space touched bottom. The employment of the heliometer which Bessel introduced was the main source of our knowledge of the distances of stars until the end of the nineteenth century, and resulted in fairly satisfactory determination of the parallaxes of nearly one hundred stars. For the part of space nearest to us this survey is sufficiently complete for us to infer the average distances of the stars from one another—2½ to 3 parsecs. The parallax determinations of double stars of known orbits lead to the result that the masses of stars have not a very great range, but lie between forty times and one-tenth of the mass of the sun.

When the absolute luminosities of the stars the distances of which have been measured are calculated, it is found that, unlike the masses, they exhibit a very great range. For example, Sirius radiates forty-eight times as much light as the sun, and Groombridge 34 only one-hundredth part. This does not represent anything like the complete range, and Canopus, for example, may be ten thousand times as luminous as the sun. But among the stars near the solar system, the absolute luminosity appears to vary with the type of spectrum. Thus Sirius, of type A, a blue hydrogen star, is forty-eight times as luminous as the sun; Procyon of type F5—bluer than the sun, but not so blue as Sirius—ten times; α Centauri, which is nearly of solar type, is twice as luminous. 61 Cygni of type K5—redder than the sun—one-tenth as luminous; while the still redder star of type Ma, Gr 34, is only one-hundredth as luminous. In the neighbourhood of the solar system one-third of the stars are more luminous and two-thirds less luminous than the sun. The luminosity decreases as the type of spectrum changes from A to M, *i.e.* from the blue stars to the red stars.

These three results as to the density in space, the mass, and the luminosity have been derived from a very small number of stars. They show the great value of accurate determinations of stellar parallax. So soon as the parallax is known, all the other observational data are immediately utilisable. At the commencement of the present century the parallaxes of perhaps eighty stars were known with tolerable accuracy. Happily the number is now rapidly increasing by the use of photographic methods. Within the last year or two, the parallaxes of nearly two hundred stars have been determined and published. This year a committeee of the American Astronomical Society, under the presidency of Prof. Schlesinger, has been formed to co-ordinate the work of six or seven American and one or two English observatories. The combined programme contains 1100 stars, of which

400 are being measured by more than one observatory. We may expect results at the rate of two hundred a year, and may therefore hope for a rapid increase of our knowledge of the stars within our immediate neighbourhood.

Velocities in the Line of Sight.

The determination of radial velocities was initiated by Huggins in the early 'sixties, but trustworthy results were not obtained until photographic methods were introduced by Vogel in 1890. Since that time further increase in accuracy has been made, and the velocity of a bright star with sharp lines is determinable (apart from a systematic error not wholly explained) with an accuracy of ¼ kilometre per second. As the average velocities of these stars are between 10 and 20 kilometres a second, the proportional accuracy is of a higher order than can be generally obtained in parallax determinations or in other data of sidereal astronomy. A number of observatories in the United States and Europe, as well as in South America, the Cape, and Canada, are engaged in this work. Especially at the Lick Observatory under Prof. Campbell's direction, the combination of a large telescope, a well-designed spectroscope, and excellent climatic conditions have been utilised to carry out a bold programme. At that observatory, with an offshoot at Cerro San Christobal in Chile, for the observations of stars in the southern hemisphere, the velocities of 1200 of the brightest stars in the sky have been determined. Among the results achieved is a determination of the direction and amount of the solar motion. The direction serves to confirm the results from proper motions, but the velocity is only obtainable accurately by this method. This quantity, which enters as a fundamental constant in nearly all researches dealing with proper motion, is given by Campbell at 19·5 kilometres per second, or 4·1 times the distance of the earth from the sun per annum, though there is some uncertainty arising from a systematic error of unknown origin.

The observations of radial velocities have shown within what limits the velocities of stars lie and have given a general idea of their distribution. The most important result, and one of a somewhat surprising character, is that the mean velocities of stars, the motion of the sun being abstracted, increase with the type of spectrum. Thus the stars of type B, the helium stars, the stars of the highest temperature, have average radial velocities of only 6·5 kilometres per second; the hydrogen stars of type A have average velocities of 11 kilometres per second; the solar stars of 15 kilometres per second; while for red stars of types K and M it has increased slightly more to 17 kilometres per second. Further, the few planetary nebulæ—*i.e.* condensed nebulæ with bright line spectra—have average velocities of 25 kilometres per second. There can be no question of the substantial accuracy of these results, as they are closely confirmed by discussions of proper motions. They are, however, very difficult to understand. On the face of it, there does not seem any reason why stars of a high temperature should have specially high velocities. A suggestion has been thrown out by Dr. Halm that as the helium stars have greater masses, these results are in accordance with an equi-partition of energy. But the distances of stars apart is so great that it seems impossible that this could be brought about by their interaction. Prof. Eddington suggests that the velocities may be an indication of the part of space at which the stars were formed (*e.g.* stars of small mass in outlying portions), and represents the kinetic energy they have acquired in arriving at their present positions.

The stars the radial velocities of which have been determined are, generally speaking, brighter than the fifth magnitude. Fainter stars are now being observed. At the Mount Wilson Observatory, Prof. Adams has determined the velocities of stars of known parallaxes, as there are great advantages in obtaining complete data for stars where possible. Extension of line-of-sight determinations to fainter stars is sure to bring a harvest of useful results, and a number of great telescopes are engaged, and others will shortly join in this important work.

Proper Motions.

As proper motions are determined by the comparison of the positions of stars at two different epochs, they get to be known with constantly increasing accuracy as the time interval increases. The stars visible to the naked eye in the northern hemisphere were accurately observed by Bradley in 1755. Many thousands of observations of faint stars down to about 9·0m. were made in the first half of the nineteenth century. An extensive scheme of re-observation was carried out about 1875 under the auspices of the Astronomische Gesellschaft. A great deal of re-observation of stars brighter than the ninth magnitude has been made this century in connection with the photographic survey of the heavens. For the bright stars all available material has been utilised and their proper motions have been well determined, and for the fainter stars this is being gradually accomplished.

Proper motions differ widely and irregularly in amount and direction. Herschel observed a tendency of a few stars to move towards one point of the sky, and attributed this sign of regularity to a movement of the solar system in the opposite direction. But puzzling differences given by different methods remained unexplained until the difficulty was resolved by Prof. Kapteyn in a paper read before this section of the British Association at its meeting in South Africa ten years ago. He showed that the proper motions had a general tendency towards two different points of the sky and not towards one only, as would be expected if the motions of the stars themselves were haphazard, but viewed from a point in rapid motion. He concluded from this that there was a general tendency of the stars to stream in two opposite directions. It is interesting to notice that this great discovery was made by a simple graphical examination of the proper motions of stars in different regions of the sky, after the author had spent much time in examining and criticising the different methods which had been adopted for the determination of the direction of the solar motion. The subject was brought into a clearer and more exact shape by the analytical formulation given to it by Prof. Eddington, and after him by Prof. Schwarzschild.

This star-streaming is corroborated by observations of velocities in the line of sight. It applies—with the exception of the helium stars—to all stars which are near enough for their proper motions to be determinable. We may say with certainty that it extends to stars at distances of two or three hundred parsecs; it may extend much further, but I do not think we have at present much evidence of this. Prof. Turner pointed out that the convergence of proper motions did not necessarily imply movements in parallel directions, and suggested that the star-streams were movements of stars to and from a centre. The agreement of the radial velocities with the proper motions seems to me to be opposed to this suggestion, and to show that star-streaming indicates approximate parallelism in two opposite directions in the motions of the stars examined. As the great majority of these stars are comparatively near to us, it is possible that this

parallelism is mainly confined to them, and indicates the general directions of the orbital motions of stars in the neighbourhood. An attempted explanation on these lines, as on Prof. Turner's, implies that the sun is some distance from the centre of the stellar system.

A discovery of an entirely different character was made by Prof. Boss in 1908. He spent many years in constructing a great catalogue giving the most accurate positions and motions of 6200 stars obtainable from all existing observations. This catalogue, which was published by the Carnegie Institute, was intended as a preliminary to a still larger one which would give the accurate positions and motions of all the stars down to the seventh magnitude. In the course of this work Prof. Boss found that forty or fifty stars scattered over a considerable region of the sky near the constellation Taurus were all moving towards the same point in the sky and with nearly the same angular velocity. He inferred that these stars were all moving in parallel directions with an equal linear velocity, and the supposition was verified, in the case of several of them, by the determination of their radial velocities. From these data he was able to derive the distance of each star and thus its position in space. The existence of a large group of stars, separated from one another by great distances, and all having the same motion in space, is a very remarkable phenomenon. It shows, as was pointed out by Prof. Eddington, how small is the gravitational action of one star on another, and that the movement of each star is determined by the total attraction of the whole mass of the stars. Several other interesting moving clusters have been found since. For all the stars belonging to these clusters, the distances have been found, and from them luminosities and velocities of individual stars, particulars which are generally only obtainable for stars much nearer to us.

Proper motions are the main source of our knowledge of the distances of stars which are beyond the reach of determination by annual parallax. If a star were known to be at rest its distance could be calculated from the shift of its apparent position caused by the translation of the solar motion. As the solar system moves 410 times the distance of the earth from the sun in a century, this gives a displacement of 1″ for a star at the distance of 500 parsecs. This method has been applied by Kapteyn to determine the distances of the helium stars, as their velocities are sufficiently small to be neglected in comparison with that of the solar system. But generally it is only possible to find the mean distances of groups of stars of such size that it may be assumed that the peculiar motions neutralise one another in the mean. For example, the average distance of stars of type A, or stars of the fifth magnitude, or any other group desired may be found. In this way Kapteyn has found from the Bradley stars that the mean parallax of stars of magnitude m is given by the formula

$$\log. \pi_m = -1{\cdot}108 - 0{\cdot}125\, m.$$

In conjunction with another observational law which expresses the number of stars as a function of the magnitude, this leads to a determination of the density of stars in space at different distances from us, and also of the "luminosity law," *i.e.* the percentage of stars of different absolute brightness. Profs. Seeliger and Kapteyn have shown in this way that there is a considerable falling off of star-density as we go further from the solar system. It seems to me very necessary that this should be investigated in greater detail for different parts of the sky separately. A general mathematical solution of general questions which arise in the treatment of astronomical statistics has been given by Prof. Schwarzschild. His investigations are of the greatest value in showing the exact dependence of the density, luminosity, and velocity laws on the statistical facts which can be collected from observation. The many interesting statistical studies which have been made are liable to be rather bewildering without the guidance furnished by a general mathematical survey of the whole position.

When the proper motions are considered in relation to the spectral types of the stars, the small average velocities of the hydrogen stars and still smaller ones of the helium stars found from line-of-sight observations are confirmed. If stars up to a definite limit of apparent magnitude, say, to 6·0m., or between certain limits, say 8·0m. and 9·0m., are considered, then the solar stars are found to be much nearer than either the red or the blue stars. Thus both red and blue stars must be of greater intrinsic luminosity than the solar stars. As regards blue stars, this agrees with results given by parallax observations. But the red stars appear to consist of two classes, one of great and one of feeble luminosity, and it does not seem that a sufficient explanation is given by the fact that a selection of stars brighter than any given apparent magnitude will include the very luminous stars which are at a great distance, but only such stars of feeble luminosity as are very near.

The significance of these facts was pointed out by Prof. Hertzsprung and Prof. Russell. They have a very important bearing on the question of stellar evolution, a subject for discussion at a later meeting this week. From the geometrical point of view of my address these facts are of importance in that they help to classify the extraordinarily large range found in the luminosities of stars. Putting the matter somewhat broadly, the A stars, or hydrogen stars, are on the average intrinsically 5 magnitudes brighter than the sun, whilst the range in their magnitudes is such that half of them are within ¾ magnitude of the mean value. The stars of type M, very red stars, are of two classes. Some of them are as luminous as the A stars, and have a similar range about a mean value 5 magnitudes brighter than the sun. Others, on the contrary, have a mean intrinsic brightness 5 magnitudes fainter than the sun and with the same probable deviation of ¾ magnitude. Between the types M and A there are two classes the distance apart of which diminishes as the stars become bluer. The facts in support of this contention are very forcibly presented by Prof. Russell in NATURE in May, 1914. If this hypothesis is true, and it seems to me there is much to be said in its favour, then the apparent magnitude combined with the type of spectrum will give a very fair approximation to the distances of stars which are too far away for their proper motions to be determinable with accuracy.

In dealing with the proper motions of the brighter stars, the sky has been considered as a whole. Now that the direction and amount of the solar motion are known, we may hope that, as more proper motions become available, the different parts of the sky will be studied separately. In this way we shall obtain more detailed knowledge of the streaming, and also of the mean distances of stars of different magnitudes in all parts of the sky, leading to a determination of how the density of stars in space changes in different directions. A second line of research which may be expected to give important results is in the relationship of proper motions to spectral type. There is in preparation at Harvard College by Miss Cannon, under Prof. Pickering's direction, a catalogue giving the type of spectrum of every star brighter than the ninth magnitude. It would be very desirable to determine the proper motions of all these stars. If all the material available is examined it should be possible to do this to a very large extent.

Photometry and Colour.

For the more distant parts of the heavens proper motions are an uncertain guide, and we must depend on what can be learned from the light of the stars by means of stellar photometry, determinations of colour, and studies of stellar spectra. Speaking generally, we attempt to discover from the nearer stars sufficient about their intrinsic luminosities to enable us to use the apparent magnitude as an index of the distances of the stars which are further away. The most striking example is found in Prof. Hertzsprung's determination of the distance of the small Magellanic cloud. From a knowledge of the characteristics of the Cepheid variables found in this cloud by Miss Leavitt, and their apparent magnitude, he deduced the distance of the cloud as 10,000 parsecs.

Much attention has been given of late years to stellar photometry. In 1899 Prof. Pickering published the Revised Harvard Photometry giving the magnitudes of all stars brighter than 6·5m. In 1907 Messrs. Müller and Kempf completed a determination of 14,199 stars of the northern hemisphere brighter than 7·5m. In 1908 a catalogue of 36,682 stars fainter than 6·5m. was published at Harvard. These determinations derive additional importance as they give the means of standardising estimates of magnitude made by eye, particularly the many thousands of the Bonn Durchmusterung.

By the labours of Prof. Pickering and his colleagues at Harvard, Prof. Schwarzschild, Prof. Parkhurst at Yerkes, Prof. Seares at Mount Wilson, and others, the determinations of the magnitudes of stars by photography has made rapid strides. As yet no complete catalogues of photographic magnitude corresponding to the Revised Harvard Photometry have been published, though considerable parts of the sky and special areas, such as the Pleiades, have been carefully studied. The determination of the photographic magnitudes of any stars which may be required is, however, a comparatively simple matter when the magnitudes of sufficient standard stars have been found. A trustworthy and uniform scale has been to a large extent secured by the use of extra-focal images, gratings, and screens in front of the object glass, and the study of the effects of different apertures and different times of exposure.

At Harvard and Mount Wilson, standard magnitudes of stars near the north pole have been published extending to nearly the twentieth magnitude. In the part of the range extending from 10·om. to 16·om. these agree very satisfactorily. There is, however, a difference of 0·4m. in the scale between 6·om. and 10·om. which needs to be cleared up.

A uniform and accurate scale of magnitude is of fundamental importance in counts of the numbers of stars. Such counts aim at the determination of two things: (1) how the numbers vary in different parts of the sky, and (2) what is the ratio of the number of stars of each magnitude to that of the preceding magnitude in the same area of the sky. The counts of stars from the gauges of Sir William and Sir John Herschel, those of the stars contained in the Bonn Durchmusterung, those made by Prof. Celoria, and the recent counts of the Franklin-Adams plates by Dr. Chapman and Mr. Melotte, all agree in showing a continuous increase of stars as we proceed from the pole of the galaxy to the galaxy itself. The importance of this fact is that it shows a close connection between the Milky Way and the stars nearer to us. The Milky Way is not a system of stars beyond the others, but is the primary feature of our "island universe."

Photometric observations have acquired additional importance from the differences between photographic and visual magnitudes. The ordinary plate is more sensitive to blue light than the eye, and the difference between the photographic and visual (or photo-visual) magnitude of a star is an index of the colour. The colour index is found by observation to be related very closely to the type of spectrum. Prof. Seares has shown from the colour indices that as the stars become fainter they become progressively redder. Prof. Hertzsprung has found the same thing by the use of a grating in front of the object glass. Among stars of 17·om. visual magnitude, Seares found none with a colour index less than 0·7; this is approximately the colour index of a star of solar type, *i.e.* near the middle of the range from blue stars to red stars.

There are three ways in which this may occur. The stars may be bright but very distant red stars; or they may be faint red stars, like those in the immediate neighbourhood of the sun; or there may have been an absorption of blue light. It is not possible to say in what proportion these causes have contributed. The red stars of 9·om. and 10·om. are nearly all very luminous but distant bodies, but it seems likely that stars of 17·om. will contain a greater proportion of stars of small luminosity.

The absorption of light in space is very small, and as yet imperfectly determined. Prof. Kapteyn and Mr. Jones, by comparing the colour indices of stars of large and small proper motion, make the difference between the absorption of photographic and visual light as 1m. in 2000 parsecs. The question has been examined directly by Prof. Adams, who has obtained spectra of near and distant stars which are identical as regards their lines, and has examined the distribution of the continuous light. This direct method of comparison showed that the more distant star was always weaker in violet light. But as both these investigations show that very luminous stars are intrinsically somewhat bluer than less luminous stars of the same spectral type, the two causes require further research for their disentanglement. The question is of importance, as it may serve in some cases to determine the distances of very remote bodies the type of spectrum of which is known.

It must be admitted that we are as yet very ignorant of the more distant parts of the "island universe." For example, we can make little more than guesses at the distance of the Milky Way, or say what part is nearest to us, what are its movements, and so on. But, nevertheless, the whole subject of the construction of the heavens has been opened up in a remarkable manner in the last few years. The methods now employed seem competent to produce a tolerably good model showing the co-ordinates and velocities of the stars as well as their effective temperatures and the amount of light they radiate. Industry in the collection of accurate data is required, along with constant attempts to interpret them as they are collected. The more accurate and detailed our knowledge of the stellar system as it is now, the better will be our position for the dynamical and physical study of its history and evolution.

NOTES.

THE director of the Meteorological Office reports that information has been received from the Seismological Observatory at Eskdalemuir, Scotland, of the record of a large earthquake which occurred at 1 a.m. on Tuesday, September 7. The computed position of the epicentre is lat. 9° N., long. 86° W., with a possible error of 10°. The position mentioned is in the Pacific Ocean, about 70 miles from Cape Blanco

in Costa Rica, and a circle of 10° radius drawn from this point as centre includes a portion of Central America and the Isthmus of Panama.

A REUTER message from Paris states that the Ministry of Foreign Affairs has sent to the Academy of Sciences a note reporting the discovery of mineral springs in Colorado containing radium in such large quantities that they may lead to the industrial extraction in America of radium, and the reduction of price to less than one-quarter the present rate per gram.

THE Ministry of Munitions announces that the Munitions Inventions Branch, which was recently constituted by the Minister of Munitions to deal with projects for inventions relating to munitions for warfare on land, or matters appertaining thereto, has now been removed from Armament Buildings, Whitehall, to accessible and commodious quarters in Princes Street, Storey's Gate, S.W. (hitherto the premises of the Whitehall Club), to which all future communications should be addressed. The department is now in working order, and is already dealing with a large number of proposals. The comptroller, Mr. E. W. Moir, is being assisted in this work by an advisory panel of scientific experts, whose names were announced in NATURE of August 19 (p. 678). This body is now at work in committees, and every proposal receives consideration from them.

IN commemoration of Capt. Cook, a tablet has been placed on the school at Great Ayton, Cleveland, where the navigator received his education; a scholarship has also been established at Marton, in the same neighbourhood, which was Capt. Cook's birthplace. The cost of both has been provided out of the surplus of the fund raised for the erection of the Cook memorial in London.

WE are informed that Mr. A. Gibb Maitland, Government Geologist and Director of the Geological Survey, Western Australia, has been appointed President of the Royal Society of Western Australia for the session 1915–16.

WE learn from the Allahabad *Pioneer Mail* that Dr. N. Annandale, superintendent of the Indian Museum, Calcutta, is to spend the greater part of his six months' leave of absence in Siam and Japan, studying the fauna of the lake regions, and that he will prepare and submit a report on the geological and entomological collections in the two countries referred to.

WE are glad to learn from Cambridge that the announcement in the *Times* of September 2 that Capt. James Romanes had been killed at the Dardanelles on August 31 is incorrect. A telegram from Gibraltar states that Capt. Romanes is returning home slightly wounded.

WE notice with much regret the announcement of the death, on September 4, at forty-four years of age, of Prof. D. T. Gwynne-Vaughan, professor of botany at University College, Reading.

THE death is announced of Julius von Payer, who, in a memorable Austro-Hungarian Arctic Expedition in 1872–74, under the leadership of Lieut. Weyprecht and himself, discovered and explored the coast of Franz-Josef Land.

THE death is announced of Mr. F. Higgins, chief engineer to the Exchange Telegraph Company. He began his career in the Post Office Telegraph Department, was Superintendent of Telegraphs in Mauritius for a time, and entered the service of the Exchange Telegraph Company in 1873, when he began to direct his attention to the development of type-printing telegraphs in the various forms now familiarly known as "tape" instruments. In this he was successful, as, besides perfecting several forms of "relays," he largely increased the speed of the instruments. In addition, he invented an instrument known as the column printer for printing on a broad band of paper. He was also the patentee of numerous inventions in electric fire alarms.

BY the death of Mr. Thomas Carrington-Smith agriculture has lost a prominent and characteristic personality, and one who did much to make British farming what it now is. He entered his farm about the middle of the 'fifties, and maintained an uninterrupted tenancy of some sixty years; thus he farmed through the prosperous times of the 'sixties, the disasters of '79, the depression of the 'nineties, and he lived to see high prices setting in once more. His long experience was placed ungrudgingly at the service of his fellow-agriculturists, and he played a considerable part in bringing about the legislation that was necessary before farmers could alter their systems of working. No industry is subject to more restrictions than agriculture, probably because farmers rarely work on more than an annual lease. Legislation is therefore necessary from time to time to effect adjustments of the various interests involved. In all this Mr. Carrington-Smith played a prominent part, and his name is associated with legislation affecting tenant right reform, swine fever, cattle disease, agricultural rates, and the sale of margarine. He was active, both on the advisory side, as chairman of the Dairy Products Committee of the Central Chamber of Agriculture, and on the administrative side, as a member of the Staffordshire County Council. He also wrote a number of papers on agricultural subjects.

WE announced, with regret, in our last number, the death of Mr. Henry Crookes, which took place after a short illness at his residence, 109 Ladbroke Road, W., on August 28. Henry Crookes was the eldest son of Sir William and Lady Crookes, and for many years he had been closely associated with his father in several branches of scientific activity. He was an associate of the Royal School of Mines, and was elected a fellow of the Chemical Society in 1902. Quiet and unassuming in disposition, his work was not largely known outside his immediate circle of friends and collaborators. Some years ago he spent a considerable time in South Africa, engaged in work connected with gold mining and the extraction of gold from residues by the cyanide process. At this time he unfortunately contracted intermittent fever, which necessitated his return to England, and the effects of which never left him. It is to this circumstance that his death at a comparatively early age is largely

due. He contributed many papers to the scientific Press. Among them are the following:—"Action of Permanganate of Potash and Acetic Acid on Bacteria in Thames Water," "Bactericidal Properties of the Emanations from Radium," "Volcanic Dust," "Photographs and Living Cultures of Bacillus Phosphorescens," "Metallic Colloids and their Bactericidal Properties." Of late years his time was occupied chiefly in the analysis of the water supply of London and several large towns in the provinces, particularly with regard to their bacterial contamination. He was the discoverer of a process for the preparation of stable colloidal solutions of silver and other metals, the valuable properties of which are now recognised by the medical profession, and he was actively engaged upon these researches and preparations up to the time of his recent fatal illness. He will be greatly missed in his particular sphere of activity. In 1883 he married the daughter of the late C. E. Spagnoletti. Our sincere sympathy is offered to his widow, as well as to Sir William and Lady Crookes for their great loss at a time when they are naturally ill able to bear the strain.

CAPT. T. P. BLACK, whose death in the Dardanelles was announced in NATURE last week, was the eldest son of the late Mr. Geo. B. Black. Born at Shotts, Lanarkshire, in 1878, he was educated at Aberdeen and Darlington, gained a scholarship to Durham University, and graduated B.A., with honours, in 1898. At this time he visited the Dardanelles, Constantinople, Skutari, and the Crimea. On his return he graduated M.A. and B.Sc., with honours, at Durham, and researched on radio-activity. He next held a science research scholarship at Strassburg, taking the Ph.D. for original work in physics carried out under Profs. Braun and Zenneck. An abstract from his doctoral dissertation, published in the *Annalen der Physik* for January, 1906, bore the title, "On the Resistance of Coils for Quick Electric Oscillations." After being an assistant at Newcastle, he became in 1906 lecturer and demonstrator in physics at University College, Nottingham. While here he was joint author of an "Introduction to Practical Physics." He was justly valued as an able teacher, and was deservedly popular with staff and students. In 1911 he accepted the registrarship of the college and so passed to new successes in a wider sphere of usefulness. Thus his soldier's death was but the crowning glory of a strenuous life, rich in distinction and promise.

THE first number of the Journal of the British Science Guild, which has just been issued, contains a verbatim report of the ninth annual meeting of the guild, held on July 1, and the address on "The National Organisation of Science," delivered on that occasion by Sir William Ramsay. It is hoped that the publication of the Journal will serve not only to keep members in touch with the results of the guild's activities in many directions, but also will be the means of securing increased support for its work. The main purpose of the guild is the promotion of scientific method and organisation in all national affairs; and there are sufficient sympathisers with this aim to increase the membership a thousandfold. The minimum annual subscription is only half a crown; life membership is obtained for two guineas, and the subscription for a life fellow is ten guineas. Any British subject is eligible to join the guild, and all who believe in the services which science can render to the arts of peace as well as those of war should give a practical sign of their conviction by becoming members or fellows. The offices of the guild are at 199 Piccadilly, London, W., and the secretary will be glad to send particulars of committees and of publications upon application.

IN the *Times* of September 4 Mr. R. C. Shaw announces the discovery at Caervoran, on the Roman Wall three miles east of Gilsland, in Northumberland, of a remarkable bronze measure of the Roman period. Such officially certified measures are very rare. On the present specimen the name of the Emperor Domitian, in whose consulate in A.D. 90 the measure was tested, has been obliterated, owing to the hatred felt towards him after his death. The measure contains 17½ sectarii, about 30 lb. of wine, or rather more than two gallons, and 8 lb. have been allowed as the weight of the material. Prof. Haverfield is uncertain whether it was really certified under the order of the Emperor, or whether it is a private venture, masquerading as official. In any case, there is no question of the date, and the discovery is of considerable antiquarian interest.

IN *Man* for September Mr. R. Grant Brown discusses the modesty of Burman women. He points out a fact familiar to all visitors to a religious fair in northern India, that women when bathing manage their scanty drapery with such dexterity that any suggestion of immodesty is avoided. The principle underlying this observance of propriety is that every Burman lady believes herself to be under the watch of twelve spirits, six of whom are good and six evil, and it is supposed that any exposure of the human form in their presence is a source of danger. Even in the wearing of the scanty tamein, or waist-cloth, she contrives to observe the laws of propriety. The only case in which decency is violated is when a woman really loses her head in the course of a quarrel with a neighbour, and both combatants roll in the gutter without any regard for decency. The explanation is that they believe that in thus humiliating an opponent they have vindicated the justice of their cause and brought the enemy into contempt.

A PAPER entitled "The History and Functions of Botanic Gardens," by Mr. A. W. Hill, assistant director of the Royal Gardens, Kew, was read by invitation at the twenty-fifth anniversary celebration of the Missouri Botanic Garden, October 15, 1914, and has been reprinted from the Annals of the Missouri Garden (Vol. ii., pp. 185–240). This paper is mainly devoted to an extremely interesting and valuable historical summary of the founding of the various botanic gardens of the world from about the year 1000 B.C. onwards, and is illustrated by nine plates, three of which are remarkably fine collotype reproductions of photographs taken in Kew Gardens.

Two important papers appear in the *American Naturalist* for August. The first of these should be carefully read by all who are interested in problems of heredity. Herein Mr. E. M. East discusses at some length "The Chromosome View of Heredity and its Meaning to Plant-Breeders." He contends that the maximum possible difficulty in the improvement of animals, and plants, by hybridisation, usually depends directly upon the chromosome number. This being so, then there can be no question as to the importance of determining the number of chromosomes in a species before beginning a complex plant-breeding problem, and thus being able to comprehend the maximum possible difficulties that may be encountered. In the second paper Prof. A. C. Eycleshymer discusses the origin of bilaterality in vertebrates. From a study of the early embryonic stages he is of opinion that neither the position nor the direction of cleavage grooves has the slightest significance as far as the setting apart of definite embryonic areas is concerned. And further, that neither the position nor the direction of the cleavage grooves enables one to predict the long axis of the embryo, so that other phenomena, which may be of service, must be looked for. These he finds in the increased cellular activity of the active pole, which can be located with the advent of the first cleavage groove. This marks the head end of the embryo. The tail end is similarly marked by the early accelerated activity of the side of the egg, indicating the forthcoming blastopore, which definitely fixes the posterior end of the embryo. It necessarily follows that the median plane of the embryo must coincide with a line passing through the centres of the two.

THERE is much that may be profitably ruminated on in the *Museums Journal* for August, even by those who have no part in the conduct of museums. More especially we refer to the views expressed at the conference of the Museums Association held in London during July, as to the relation which should exist between museums and the various grades of educational institutions. In Manchester, where so many of the school buildings have been converted into military hospitals, a number of teachers have been sent to the museums to receive a thorough course of instruction on the various aspects of the museums to which they are sent, in order that, when peace returns to us, they may the more efficiently utilise the museums as sources of education. Many valuable suggestions for the further widening of the spheres of usefulness of museums were also made, some of which, at any rate, might well receive immediate attention. The address of the president, Mr. E. Rimbault Dibdin, might be read with much profit by the peace cranks who just now are so busy.

MR. G. B. WALSH makes some interesting observations on the causes determining the survival and extermination of insects in the manufacturing districts of Yorkshire in the *Entomologist's Monthly Magazine* for August. Drainage, cultivation, and moorland fires have done much, but blast-furnaces and chemical works have done more, to bring about the extinction of many insects that were once common in the areas surveyed. Some have contrived to thrive under the most adverse conditions. Thus he relates how two very local beetles, moorland species—*Miscodera arctica* and *Pterostichous vitreus*—are to be found, in some numbers, in a marsh traversed by a fœtid stream, and stinking most abominably of hydrogen sulphide. A slag heap bounds the marsh on either side, which receives the overflow from a neighbouring chemical works, while dust from calcining and blast-furnaces fills the air, which is saturated with the odour of rotten eggs. How insects the natural home of which is the breezy moorland can contrive to thrive under such appalling conditions is indeed a mystery. Specimens taken from this new habitat should be carefully compared with others obtained from the moorland to discover, if possible, whether any adaptations to the new environment have taken place.

THE accurate zoning of Carboniferous strata in the British Isles has received general attention since the pioneer work of A. Vaughan on the Avon section. L. B. Smyth, lecturer on palæontology in the University of Dublin, has now (Sci. Proc. R. Dublin Society, vol. xiv., 1915, p. 535) cleared up some obscure points in the sequence in the north of the county of Dublin, where a river from the Devonian land-surface entered the Carboniferous sea. A correlation is made between these Irish deposits and those of the English Lake District, described by E. J. Garwood. Several new species of corals, and a new genus, Arachniophyllum, are described. The old Arachnophyllum, by the by, has been absorbed in Strombodes; but it might have been well to direct attention to this, the new generic name being almost identical.

FROM a new consideration of the "Interglacial Gorges of Six Mile Creek at Ithaca, New York" (Journ. of Geology, vol. xxiii., 1915, p. 59), J. L. Rich and E. A. Filmer conclude that at least three glacial epochs are indicated, "separated by periods of time longer than that since the last epoch." The great Wisconsin ice-extension entered the interglacial stream-gorges, and deposited its drift there, without appreciably modifying their walls.

F. CHAPMAN describes a new genus of dibranchiate cephalopods, Notosepia, from the Oligocene of Victoria, Australia (Proc. R. Soc. Victoria, vol. xxvii., 1915, p. 357). Young forms have a recurved mucro at the termination of the pro-ostracum, recalling the Eocene Belosepia, while this becomes, in adult specimens, straightened towards the type known in the modern Sepia.

STUDENTS of meteorites will be glad to note the record of the rare calcium sulphide, Oldhamite, which crystallises in the cubic system, in the "carbonaceous chondrite" of Indarch, Russia (G. P. Merrill, Proc. U.S. Nat. Museum, vol. xlix., 1915, p. 109). Mr. Merrill quotes its occurrence in five other meteorites of varied composition, and points out that it may prove to be more widely diffused, since it is usually inconspicuous.

THE use of antiseptics or disinfectants for the treatment of wounds is limited by several factors. Thus many potent germicides may be irritating to the tissues

and poisonous to the system, *e.g.* mercuric chloride. The efficiency of a disinfectant is probably always reduced more or less by the albuminous constituents of the discharge from the wound. In a paper entitled "On the Use of Certain Antiseptic Substances in the Treatment of Infected Wounds" (*Brit. Med. Journal*, August 28, 1915, p. 318), by Dr. H. D. Dakin, of the Herter Laboratory, New York, some of the limitations of the commonly-used substances are detailed, and means for obviating them are discussed. Thus hypochlorite of soda is very active, but always contains free alkali, which is irritating. If, however, it be mixed with a weak polybasic acid, the latter will neutralise the free alkali without decomposing the hypochlorite. A solution of suitable concentration for direct application to wounds, containing 0·5–0·6 per cent. of sodium hypochlorite, may be prepared as follows:—140 grams of dry sodium carbonate (Na_2CO_3), or 400 grams of the crystalline salt (washing soda) is dissolved in 10 litres of tap-water, and 200 grams of chloride of lime (bleaching powder) are added. The mixture is well shaken, allowed to stand for half an hour; the clear liquid is then syphoned off from the precipitate of calcium carbonate and filtered through cotton-wool. To the clear filtrate 40 grams of boric acid are added, and when dissolved the resulting solution is ready for use, but it should not be kept longer than one week. It may be used for continued irrigation of wounds up to 1, or even 2, litres a day without harm. Other chlorinated organic compounds (certain chloroamides) are also being tested.

DISCUSSIONS of the anemographic observations recorded at Jubbulpore from May, 1889, to April, 1900, and at Belgaum from May, 1881, to April, 1904, are given as Nos. 5 and 6 of the Memoirs of the Indian Meteorological Department, vol. xix. The discussions have been carried out by W. A. Harwood, and an introduction is given by Dr. G. T. Walker, Director-General of Observatories in India. Some notes were left by Sir John Eliot on the Belgaum observations. Faulty exposure and inefficient working are alluded to as occasioning some discrepancies. Jubbulpore is at an elevation of 1327 ft. above sea-level, and a detailed description is given of the station. The climate is divided into three seasons: the dry, cool season, from October to February; the dry, hot season, from March to May; and the rainy season, from June to September. The variation of wind direction and velocity is given for each of these seasons and for the year, also for the several hours in each month, and details are shown both in a tabular form and graphically. Storm winds are also dealt with. Belgaum is 2539 ft. above sea-level, and the observations are similarly treated to those at Jubbulpore, the discussion being made separately for the cool season commencing in October and ending in February; the hot season in March, April, and May; and the south-west monsoon season in June and September.

IN the Journal of the Royal Statistical Society for July Mr. S. Rosenbaum analyses the effects of the war on the overseas trade of the United Kingdom. In order to estimate the probable value of the trade in each of the five months, August-December, 1914, if no war had taken place, the trade in January-July is multiplied by the average ratio, for each of the months, in the years 1904–13. A basis is thus obtained for separating, approximately at least, the effects of the war from the normal course of trade. So estimated, the collapse of the export trade due to the war was about 97,000,000*l.* in the first five months—a decline that was widely spread over nearly all classes of exports. If exports are valued on the basis of peace prices this decline is slightly lessened. Of the total export trade lost about 22,000,000*l.* would have taken place with enemy countries. As regards imports, the shrinkage was approximately 67 millions, or about one-fifth of the expected imports, but the ratio was a steadily declining one. It must be remembered, however, in this case that a considerable rise in prices partly masked the decline; in volume the decline must have been about one-fourth. Details are given in the paper for the several classes of exports and imports, and in the latter part some analysis is presented of the figures for January–April, 1915. During these months the state of affairs was largely altered. While exports were still heavily down, in February, March, and April the value of imports was greater than in the corresponding months of 1914, and this was a real increase, not in values only, but also in volume.

IN the same issue of the Journal there is a paper by Mr. Bernard Mallet and Mr. Strutt, in continuation of a paper published by Mr. Mallet in 1908, on the multiplier necessary for converting the value of estates passing at death, and declared for estate duty, into the value of capital wealth in the hands of the living. The value of the multiplier, 24, reached in the earlier paper was thought on several grounds to be too low, and the problem has now been re-attacked. The chief source of error was the assumption of too high a rate of mortality. Taking figures more nearly corresponding to the estate-leaving class the multiplier is raised to 28. Rather unexpectedly an often-suggested source of possible error—gifts *inter vivos*—it is argued, does not, in fact, affect the results, though this conclusion was disputed in the discussion that followed. A further amendment of the mortality rates used, made in reply to criticisms offered, suggests that the multiplier might be further raised to 30. Even this multiplier gives a value of total capital in the hands of the living of only 10,776,000,000*l.*, a value some two or three thousand millions less than that of several other estimates.

IN his concluding article on modern bullets in war and sport in *Engineering* for August 27, Fleet-Surgeon C. Marsh Beadnell says that hard-nosed bullet wounds of the lung are not as a rule fatal. When a hollow organ such as the stomach is perforated by a bullet, it sustains more damage if it contains fluid than if empty. The author fired a 0·303 bullet at a sheep's stomach, in the one case when it was full of water, and in the other case when empty, with the following results. The aperture in each wall of the empty organ was 0·2 in.; the aperture in the first wall of the full stomach was also 0·2 in.,

but that in the second wall was 0·7 in. From this it follows that a man hit after a full meal would have less chance of recovery than had this occurred when the organ was empty. Bullet wounds of the lung, provided no large vessels are touched, are seldom fatal in man or beast. The author has seen as many as a dozen men in one ward of a base hospital all convalescent from lung injuries.

In an article in *Engineering* for September 3, Mr. William Hovgaard discusses the *Lusitania* disaster, and draws therefrom the following conclusions:—(1) The principle of transverse subdivision should be considered as fundamental in the design of all vessels, merchant ships as well as warships, simply because the longitudinal stability is always much greater than the transverse, and in sea-going ships is generally about one hundred times as great. (2) Longitudinal subdivision is intrinsically pernicious, on account of the small transverse stability of all ordinary vessels, and should be used only where absolutely necessary. (3) All wing compartments, where such must be fitted, should either be so small that their heeling effect when flooded will be negligible, or, if that is impracticable, as may be the case in warships and auxiliary cruisers, they should be in permanent connection with corresponding compartments on the other side of the ship, so as to eliminate the heeling effect automatically. Provision may be made, in addition, for pumping water into the side compartments. In pure merchant vessels, no side bunkers or other longitudinal compartments of so large a volume as to require such means of compensation should be allowed.

The *Engineer* for September 3 has an article on the employment of women as machinists, with special reference to the various shell factories organised by Sir William Beardmore. About 800 girls are now employed in these factories, and the number will shortly be very largely increased. Some of these girls have now been at work for about four months, and were first trained by special instructors selected from men employed in other departments of Messrs. Beardmore's works, assisted by skilled operators sent down by the makers of several of the machines. These girls were found to be capable of a good output on many of the operations after only a week's instruction. Lady superintendents are in charge of the place night and day, and a good mess-room is provided for meals. All the operations, with one exception, in the making of 18-pounder shells are carried out by the girls. The output on some of the operations exceeded expectation owing to the keenness of the girls, so much so that some of the machines provided have actually been found to be superfluous, and other machines have been shown to be capable of more work than had ever been believed to be possible. There is plenty of such labour available in the country, and all the women are moved by the keenest spirit of patriotism. We trust that employers will not hesitate to fill in their blanks from this source.

Motor barges, which stir up the mud and discharge large quantities of oil in the Grand Canal, in the neighbourhood of Ballinasloe, Co. Galway, will apparently soon bring about the extinction of some of the rarer aquatic mollusca. This at any rate is the opinion, founded on experience, of Mr. R. A. Phillips, who contributes a short but valuable account of the mollusca of South Galway to the *Irish Naturalist* for August.

OUR ASTRONOMICAL COLUMN.

Comet Notes.—Comet Mellish (1915 *a*) is moving north and towards the earth, and will be nearest about October 26 (47 million miles). It is also rapidly getting away from the sun, and its brightness is diminishing. J. Braae and J. Fischer-Petersen have extended the ephemeris given in *Astronomische Nachrichten* 4802. The comet is apparently moving nearly parallel to and only slightly S. of the line joining β Canis Majoris and β Orionis. It will make very close approach to each of these stars on September 27 and November 5 respectively. During this time its magnitude will have reduced from 7·7 to nearly 8·3. J. Braae also supplies a continuation of the ephemeris for the periodic comet Tempel II. (1915 *c*). Dr. H. Thiele, of the Bergedorf Observatory, publishes (*Astronomische Nachrichten* 4811), positions measured on August 9 and 10. It is now somewhat distant and retiring. Its declination is slowly decreasing on a path in Taurus, practically at right angles to that of 1915 *a*. For the other periodic comet at present in apparition, Winnecke's comet (1915*b*—this return was first observed by Dr. Thiele just mentioned), K. Hillebrand has extended the ephemeris given in *Astronomische Nachrichten* 4787, using slightly improved places (*Astronomische Nachrichten*, 4810). This comet has also passed perihelion, and does not come nearer than the sun's distance (about September 25). Its apparent path passed near κ Virginis (August 31), and from Virgo passes through Libra and centrally through Scorpio, bringing it near ϵ Scorpionis on October 4. During the last apparition (as 1909 *d*) it remained very faint and without observable tail or nucleus.

The Total Solar Eclipse, August 21, 1914.—Several publications dealing with this eclipse have lately come to hand. In one of these, MM. C. Benedicks and I. Fredholm describe (Ark. K. Svenska Vet' Acad., Band 10, No. 24) some photographs taken at Lundsvall with a telephoto combination (Goerz anastigmat and Zeiss teleansatz). They have devised a laboratory experiment reproducing the effect of shadow-bands which they ascribe simply to an effect of refraction in a non-homogeneous medium. Senor P. Carrasco forwards a reprint of a note referring to his observations made at Theodosia of the red line at λ 6373 (Revista R. Acad., Ciencas, January, 1915, Madrid). From Prof. Guglielmo Mengarini we have received a copy of an article which appeared in the *Nuova Antologia* (fasc. 1039, Rome), describing the operations of the Italian expedition to the Crimea. Although occupying a station in the neighbourhood of Theodosia, a fortunate break in the clouds permitted observations of totality, and the corona was photographed by Prof. Mengarini on a Lumière autochrome plate, exposed at the focus of the Fraunhofer equatorial (3 metres f. l.) loaned by Prof. Bemporad. Illustrations include reproductions of two composite corona photographs and some prominence pictures. Prof. Ricco made visual and spectroscopic observations. Prof. Palazzo employed a series of recording instruments in observations of solar radiation, terrestrial

magnetism, electric potential, and earth temperature. From the *Astronomische Nachrichten* (No. 4811) we learn that the 6-in. Repsold heliometer of the Leipsic Observatory was employed by Von Naumann, assisted by Frl. Kuschel, for measures of the position angles of the cusps at chronographically recorded instants through the greatest phase; 150 measures were obtained in about fifty-two minutes. The following corrections to the ephemerides were obtained:—

$$d\alpha = +11{\cdot}4'' \pm 0{\cdot}12'', \quad d\delta = -3{\cdot}6'' \pm 0{\cdot}08''.$$

The solar co-ordinates were taken from the *Berliner Jahrbuch*; the moon's position was derived from the Nautical Almanac.

COLOUR INDEX AND DISTANCE OF STARS.—Mr. P. J. van Rhijn, who has been working at the Mount Wilson Observatory, has presented an important memoir to the University of Groningen as thesis for doctorate dealing with the change of colour with distance and apparent magnitude, including a new determination of the mean parallaxes of the stars of given magnitude and proper motion. The stellar data employed in the paper are:—(1) Colour or photographic and visual magnitude; (2) spectral type; (3) distance. Colour and spectral type have been taken from the Yerkes actinometry. Distance has been determined according to Kapteyn's method of deriving mean parallaxes from proper motions and magnitudes, and then calculating the mean distances on the hypothesis that the logarithms of the ratio of true parallax to the most probable parallax of stars having the same magnitude and proper motion are distributed according to the law of errors. The data permitted these values to be satisfactorily obtained for the helium and second-type stars, but for the A-type paucity of parallaxes necessitated different treatment. As would be expected, Mr. van Rhijn has obtained results in good accord with those of Kapteyn, whilst the exclusion of stars with large angular motions is shown to be responsible for the opposed conclusions reached by Dr. Campbell.

Having obtained numerical expressions for the mean distances of the stars, Mr. van Rhijn proceeds to deal with the colour index. This has been taken as the summation of the effect of distance and apparent magnitude, the effect of absolute magnitude for various reasons having been given a zero coefficient. Out of the laborious calculations involved in the solution of the colour index equations the following results have emerged. The *faint* stars, and also the *distant* stars, are, *ceteris paribus, redder* than the bright stars and the near stars respectively. The increase of the colour index found being $+0{\cdot}025$m. $\pm 0{\cdot}004$ per cent. per unit of visual magnitude, and $+0{\cdot}00015$m. $\pm 0{\cdot}00003$ per cent. per unit of distance (parsec).

It is possible that the B stars and also the early A stars are immune from the distance effect. If that were so, the coefficient for the remaining spectral types would be increased to a value 6·5 times its probable error. The effect may be due either to an absorption of light in interstellar space or to an influence of absolute magnitude on colour.

RECENT STUDIES OF CERTAIN TROPICAL DISEASES.

MANY features of much interest are presented in the current number of the *Annals of Tropical Medicine and Parasitology* (vol. ix., No. 2, June 30). The opening article, by Dr. Breinl, deals with the ulcerative disease known as Gangosa, or Rhinopharyngitis mutilans, as observed by him in New Guinea. The causal agent of the disease is considered to be a new species of Cryptococcus (*C. mutilans*), of which illustrations are given in a coloured plate. The ravages due to Gangosa are forcibly demonstrated by three plates of photographs of different cases. The second paper, by Dr. H. Priestley, deals with *Theileria tachyglossi*, a protozoan parasite found in the blood and internal organs of an Echidna, *Tachyglossus aculeatus*, from the neighbourhood of Townsville, Queensland. This article is of interest as being the first record of the organism from marsupials. The parasite closely resembles *Theileria parva* of African East Coast fever in cattle. A coloured plate depicts the forms of the parasite observed.

The investigation into the causes of the prevalence of typhoid or enteric fever in Kingston, Jamaica, is ably set forth by Dr. H. H. Scott in the third paper. The mode of infection of food and milk supplies and the means of detection of unrecognised carriers of the typhoid bacillus are described, and should be of service to workers both at home and in the tropics. Water supplies and sewage disposal are also considered. The post-mortem findings and the results of cultivation of the bile from 120 consecutive autopsies are given in tabular form. Eighty more cultivations have since been made. From the total of 200 there have been six cases from which the bacillus has been isolated, apart from those subjects who showed post-mortem signs of enteric fever. There are also numerous charts showing the seasonal prevalence of the disease in Kingston.

Another paper by Dr. Breinl deals with the occurrence of various diseases prevalent on the coastal belt of British New Guinea. Eight plates of photographs illustrate the article. Certain diseases, such as malaria, are already known there, but less work has been done on others. Leprosy, filariasis, various curious fevers, juxta-articular nodules, yaws, tropical ulcers, contracting sores, destructive interdigital ulcers, and gangosa have been found among the natives. Only the regional distribution of the maladies has so far been attempted in any detail. New Guinea should provide a rich field for further research in tropical medicine.

The concluding paper is by Dr. Fantham, and deals with insect flagellates and the evolution of disease, with a plea for the recognition of the importance of comparative methods in the study of protozoology. The leishmaniases are used in illustration, and their origin from insect flagellates which are able to adapt themselves to life in vertebrates is discussed. The significance of the herpetomonad flagellate stage of Leishmania, and the existence of such a stage in man, at any rate in *L. tropica*, is indicated. The discovery of natural herpetomonads in mice by Dutton and Todd and by Fantham and Porter is recalled, as well as the occurrence of herpetomonads pathogenic to plants (Euphorbia spp.). The recent striking experiments of Laveran and Franchini on the introduction of herpetomonads into mammals, and of Fantham and Porter on the introduction of these flagellates into mammals, reptiles, amphibia, and fishes are summarised. In these experiments the evolution of the disease, that is, "leishmaniasis in the making," is revealed.

THE TALGAI SKULL.

PERHAPS the most remarkable incident of the meeting of the British Association in Australia last year was the demonstration given by Profs. Edgeworth David and Wilson to Section H in Sydney of a completely mineralised skull found in the neighbourhood of Talgai in the Darling Downs, Queensland. When war broke out and Prof. Wilson

had to devote himself to military duties, Dr. Arthur Smith was appointed acting-professor of anatomy in the University of Sydney, and Colonel Wilson most magnanimously handed over to him this most important human relic for investigation and description. With the valuable assistance of Mr. D. M. S. Watson he has succeeded in removing the matrix and fully exposing the extraordinary features of Australia's earliest known human inhabitant, perhaps a member of the earliest family to ferry across Wallace's line and tramp dogs through Papua to Queensland.

The skull has been purchased by the Hon. Joynton Smith, M.L.C., and presented by him to the University of Sydney. The formal presentation was made the occasion of a public meeting in the University on June 18, presided over by the chancellor, when Acting-Prof. Arthur Smith and Prof. David delivered addresses on the significance of the skull and its bearing upon the problems of man's antiquity in Australia.

Prof. David explained that the skull (of the Pleistocene period) was found after a flood thirty-one years ago in the bed of a creek near Talgai station, on the Darling Downs, by a stockman. From its highly mineralised state and mode of occurrence in a region where other fossil remains had also been found, the skull was of sufficiently striking geological antiquity to be grouped with the last ice epoch of the northern hemisphere. At the close of the last glacial period, gigantic animals became extinct, and probably the big animals known to have existed in Australia ages ago likewise died at the same time as those of the northern hemisphere. The discovery of the skull might serve to explain how it was that Australia, with its marsupial fauna, had an invader in the form of the dingo, which was a sort of Asiatic jackal, and "had no more right here than the Germans had in Belgium." There was the possibility of its having been brought here by early man. However, the skull was worth its weight in gold. The University of Sydney and men of science throughout the world were under a deep debt of gratitude to Mr. Smith for purchasing the skull, which was undoubtedly a priceless specimen.

Acting-Prof. Smith stated that the condition of the teeth was such as to show that the skull was a youth's, while at the same time it had many of the characteristics of an adult skull. The canine tooth of the Talgai fossil was the largest human tooth so far discovered. The extremely primitive characteristics were such as to warrant one claiming for the skull considerable importance in anthropology, and worthy of being placed with such specimens as the prehistoric Heidelberg jaw and the Piltdown skull. There was, he concluded, certain to be a great controversy concerning the latest discovery when the results of the investigation were made known.

THE RAINFALL OF JAVA.

LYING as it does midway between India and Australia, Java forms a climatological link between the two great British Dominions, and we recognise the appropriateness of the compliment implied in the choice of English as the second language in which this important outcome of Dutch enterprise is published. Tables are given of the mean monthly rainfall, number of rain days, and mean daily maximum rainfall (for each month) at 1061 stations in Java from observations taken between 1879 and 1911. Dr. van Bemmelen discusses the trustworthiness of the data, which are far from uniform. Obviously fallacious records have been eliminated, and there is reason to believe that the data here given compare well with those available for other tropical countries. Observations were made to the nearest millimetre, so that the critical rainfall which determines whether or not a day is to be counted as a rain day is 0·5 mm., or 0·02 in., *i.e.* four times the amount taken as determining a rain day in this country. As an example of the variability of monthly rainfall in Java, the case is cited of one station where in September, 1902, the rainfall was 12 mm., and in September, 1904, 896 mm. The greatest average annual rainfall recorded at any station in Java is 8305 mm., and the least 882 mm., but for both stations quoted the average was only for the short period of seven years, and experience shows that runs of seven years may occur with every year above or every year below the long-period average. The wettest year ever recorded at any station was 10,112 mm. at Sirah Kentjong, Kediri, in 1909, and the greatest fall in twenty-four hours was 511 mm. at Besokor, Semarang, on January 31, 1901.[1] Perhaps I may be pardoned if I remind those who keep metric and vulgar statistics in separate compartments of their brains that these figures are equivalent to 398·1 and 20·1 in. respectively.

The most important part of Dr. van Bemmelen's work is his series of maps of average rainfall. That he was fully alive to the difficulties in his way is made plain by his quotation of the reasons which deterred him in 1908 from making the attempt. To our mind the greatest difficulty, and one that has not been overcome, is the use of averages of varying lengths without reduction to a common period. We agree with the author that such reduction was difficult, if not impossible, in the circumstances, and that any sort of isohyetal map is better than none, and for many purposes, both scientific and economic, the maps he has produced will prove most useful. He gives a large-scale (1 : 1,000,000) map showing the position of the stations, and a series of smaller maps (scale 1 : 1,500,000) for annual rainfall, and the mean monthly rainfall of four selected seasons. These are:—(1) the mean of the three wettest months, December, January, February, when the west monsoon is blowing; (2) the mean for the two months March and April, showing the main transition; and (3) the mean for the two months May and June, when the transition is almost complete, to (4) the period of the east monsoon, represented by the mean of the three months July, August, September—the driest part of the year; finally, (5) the mean of October and November, showing the transition to the wet season again. These maps are admirably executed and most suggestive; but we are of opinion that both the climatic transitions and the geographical distribution would be more clearly suggested by maps based on the homogeneous average of, say, the last ten years, than on the data actually used. We are in hearty agreement with Dr. van Bemmelen's method of drawing isohyetal lines from such data as are available by what he aptly terms "a continual compromise between deduction and induction," the deduction being based on the recognised relationship between configuration, wind-direction, and rainfall, the induction being from the data which have been actually observed. Even where the data are as numerous, long-continued, and reasonably accurate as they are for the British Isles, the most probable distribution of rainfall can only be represented cartographically by such a "continual compromise."

HUGH ROBERT MILL.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. A. J. BALLANTYNE has been appointed lecturer on ophthalmic medicine and surgery at the Anderson College of Medicine, Glasgow, in succession to Dr. A. F. Fergus.

MR. S. H. E. BARRACLOUGH, lecturer in mechanical engineering at the University of Sydney, N.S.W., has been appointed to the chair of mechanical engineering at the same University.

MR. P. H. FRAENKEL, at present in charge of the classes in electrical engineering at the Working Men's College, Melbourne, has been appointed lecturer in electrical engineering at the University of Western Australia, Perth, W.A.

IN consequence of the war, the winter session of most of the medical schools will be begun without any ceremony or opening address. At the Middlesex Hospital Medical School, however, Dr. J. Cameron will address the students on the opening day—October 1; at the University of Leeds, on the same day, Sir William Osler will deliver the inaugural address, and at the London (Royal Free Hospital) School of Medicine for Women, Mrs. Willey, M.D., will speak.

THE City of Bradford Education Committee has issued an abridged prospectus for the forthcoming session of the Bradford Technical College day courses. These courses of study are organised to provide (*a*) diploma courses, (*b*) part-time technical courses, and (*c*) courses for professional examinations. The diploma courses afford a full training for the various branches of the textile, chemical, and engineering industries, including the underlying sciences; they extend over three (or in some cases four) years, and occupy the full time of the student. Much of the work is of an advanced character, and a special feature is the great importance attached to scientific investigation. The courses provide the necessary training for the higher positions in works. Arrangements have been made with the University of Leeds whereby students of the University or of the college have the use of certain equipment and other facilities at both institutions. The part-time technical courses are intended for those students who arrange to spend part time in the works, or who attend the college for special sudy. The diploma of the college is awarded to each day student who has been in attendance for three complete sessions subsequent to passing the entrance examination, and who has passed the college examinations in *all subjects* of the diploma course taken. The diploma courses in chemistry, and in chemistry and dyeing, extend over four years.

AGRICULTURAL TEACHING IN AMERICAN SCHOOLS.

The Essentials of Agriculture. By H. J. Waters. Pp. x+455+xxxvi. (Boston and London: Ginn and Co., 1915.) Price 1.25 dollars.

PRESIDENT WATERS tells us in his preface that the American people have decided that the public schools shall teach pupils "to think and to do," and shall give a training intimately related to the life the student expects to lead. As a necessary consequence agriculture figures largely in American schools, and we are told that wherever it is well taught it has proved to be a source of strength—whether the institution is a one-teacher country school, a high school, a college, or a university. The most successful method is to make the teaching local, taking the whole neighbourhood as the laboratory, and drawing abundantly on the local farms, gardens, orchards, and lanes, and the recognised local experts for the apparatus and materials required.

The teacher who embarks on such a course soon runs up against considerable difficulties, because none of the simple cases described in the popular book ever seem to occur in his own district; and, on the other hand, the problems in his district appear to be tantalisingly ignored by the book. It is indispensable, therefore, that the teacher's library shall contain only books by men of wide experience, and for this reason a special welcome is sure to be given to President Waters's book, for few men can claim to possess the necessary qualifications in greater degree.

The opening chapters set out briefly the principles on which the "new agriculture" rests. Under American conditions, where one or two men with modern machinery work a large farm, the man-yield is high though the acre-yield is low. Under European—including British—conditions the acre-yield is high, but the man-yield is low. What is wanted is a combination of the two. President Waters, therefore, proceeds to set out the conditions necessary for an increase in the acre-yield.

First of all, better plants and animals are needed. An account is given of the way in which improvements have already been effected in the common crops and live-stock, and the underlying principles are clearly set out. The author next discusses how plants feed and grow, and deals not only with plant food in the conventional sense but also with the water relationships of the crop, a subject to which American investigators have rightly paid considerable attention. This is followed by a section on soils, and emphasis is laid at the outset on the need for adopting a conservative policy. "We may be wasteful and careless of everything else," says the author, quoting William Brown, "but the land belongs to the Ages. We are trustees holding this land . . . and the happiness, the comfort, and the very existence of our children's children, and the millions who will follow, is dependent upon the conscientious, far-seeing wisdom with which we discharge this solemn trust." This high line is adopted by many of the most distinguished teachers of the United States, and is the key-note of much of the development work of recent years. The author follows Cyril Hopkins in working out his illustrations, and gives actual figures to show what quantities of nitrogen, phosphorus, potassium, etc., must be present in the soil in order to give a full crop. In Dr. Hopkins's experience the method works satisfactorily, although it has been the subject of much criticism. The quantities of these materials present in any ordinary soil are far in excess of the requirements of the crop, and it is necessary to assume that they are mostly in combinations unavailable for the plant, but that they become available at a certain rate per annum: 2 per cent. of the nitrogen, 1 per cent. of the phosphorus, and 0·25 per cent. of the potassium, being the rates quoted here. Naturally, a comparison can only be set up between soils of similar types under similar climatic conditions, but the actual procedure is much like the one that answers very well in this country, although based on a different principle.

The author next passes on to manures, and has much to say about the losses and wastage to which farm-yard manure is often subject. It is estimated that the amount produced in the United States each year is worth more than two billions of dollars, *i.e.*, more than the entire wheat or corn crop, and that nearly one-half is wasted. We ourselves are in no better case; the illustrations given by the author could be paralleled in this country. Fortunately the matter is being seriously taken in hand at Rothamsted and other experimental stations.

Individual crops and animals are then described, and the book closes with chapters on the business aspects of farming, and on mechanical power for farmers.

The book brings home vividly to the reader the enormous part played by the experiment stations in the development of American agriculture. The advances made during the last forty years would appear incredible if they were not accomplished

facts, and the book is so well written and so well illustrated that the student must see at once that the hope for the future lies in the close co-operation of farmers and experiment station investigators. Both in matter and in spirit it is entirely commendable. E. J. RUSSELL.

MOLLUSCS, MAMMALS, AND MEMORABILIA.

(1) *Our British Snails.* By the Rev. Canon J. W. Horsley. Pp. 69. (London: S.P.C.K., 1915.) Price 1s. net.

(2) *Land and Freshwater Mollusca of India, including South Arabia, Baluchistan, Afghanistan, Kashmir, Nepal, Burmah, Pegu, Tenasserim, Malay Peninsula, Ceylon, and other Islands of the Indian Ocean.* Supplementary to Messrs. Theobald and Hanley's Conchologia Indica. By Lieut.-Col. H. H. Godwin-Austen. Vol. ii. Part xii. December, 1914. Text. Pp. 311–442. Vol. ii. Part xii. December, 1914. Plates cxxxiii–clviii. (London: Taylor and Francis, 1914.) Price 25s.

(3) *Catalogue of the Ungulate Mammals in the British Museum (Natural History).* Vol. iv. Artiodactyla, Families Cervidæ (Deer), Tragulidæ (Chevrotains), Camelidæ (Camels and Llamas), Suidæ (Pigs and Peccaries), and Hippopotamidæ (Hippopotamuses). By R. Lydekker. Pp. xxi+438. (London: British Museum (Natural History), and Longmans, Green and Co., 1915.) Price 10s. 6d.

(4) *Nature and Science on the Pacific Coast. A Guide-book for Scientific Travellers in the West.* Edited under the auspices of the Pacific Coast Committee of the American Association for the Advancement of Science. Pp. xii+302+plates. (San Francisco: Paul Elder and Co., 1915.) Price 1.50 dollars.

(1) CANON HORSLEY'S clever little manual encourages food-thrift by pointing out that "all snails are edible and nutritious," even the garden snail being indeed "insipid; but as nourishing as calf's-foot jelly." Under the general heading of British snails it includes the slimy slug with scanty shell, and the aquatic bivalved pearl-bearing Unio. The statement that "there are but eighty-two land and forty-five freshwater shells in Britain" is slightly modified by the subsequent discrimination of forty-nine British freshwater species, including *Neritina fluviatilis,* for which, as recently shown, the generic name should preferably be de Montfort's Theodoxus. A gentle warning against the extirpation of rare species might have been added, to qualify the impulse to the study of natural history in general given by such remarks as the following: "If you want to make a collection, whether of dried plants, of insects, of shells, or of anything else, you must cultivate ways of order and method and neatness in the arrangement of your collection; and then your increased powers of observation, of comparison, and of method" will, the author believes, augment in you the virtues of prudence, justice, temperance, and fortitude.

(2) If you want to make a collection of books, and to cultivate order and neatness in the arrangement, what sort of temperate language will you apply to persons who publish the text of an important work in octavo and the plates in quarto? This is the afflicting arrangement in the otherwise admirable treatise on the land and freshwater mollusca of India. Doubtless the distinguished surveyor and veteran naturalist is responsible for the matter, not the form, of his book.

The book opens with a discussion of the Limacidæ, and a statement that "representatives of this family have not hitherto been described from the Himalayan range." But the bulk of this part xii. is concerned with a most industrious survey of the genus Alycæus, continued from Part vii., published in 1897. Here Col. Godwin-Austen notes that his outline of the sub-family Alycæinæ (vol. i., part v.) in 1886 now requires amplification because in the intervening twenty-eight years the number of known species has very greatly increased. That the members of the genus are not usually of gigantic size may be inferred from *Alycæus (Raptomphalus) magnificus* n. sp., since this magnificent and "very beautiful" species is less than a fifth of an inch, 4·25 mm., in its major diameter. Through quotation of original descriptions, intended to be exact, measurements are variously referred to mm., mill., in., unc., sometimes with rather confusing results. Thus *Alycæus cucullatus,* Theobald, is credited with a "Diam. maj. 21, diam. min. 20; alt. 21 unc.," and the notice that "This is a remarkably fine species." It certainly must be if it has a breadth of 21 inches and an equal height, but the figure magnified "×8," measures only 1⅝ in. across, with a height less than an inch. Even by a sprinkling of decimal points the dimensions cannot be harmonised with the illustration. Among matters of general interest, as apart from technical descriptions, special reference may be made to the discussion of *Alycæus (Cycloryx) graphicus,* illustrative of variation in shell-character in connection with distribution.

(3) By its title "Mollusca to Man," a well-known volume long ago hinted at a lowly lineage for humanity itself. This notice may therefore be excused for passing abruptly from slugs and snails to the graceful deer and ponderous hippo-

potamus with which the Museum catalogue of Ungulate Mammals is concerned in its fourth volume. This work closes the scientific career of Richard Lydekker. Its accuracy is guaranteed by the trusty supervision of Oldfield Thomas. The facile unwearying pen of its actual author writes no more. A preface by Dr. Harmer commemorates Lydekker's devotion to work, and the esteem in which he was held by his colleagues.

The volume has one feature challenging at least a note of admiration. It abounds in such names as *Moschus moschiferus moschiferus, Odocoileus virginianus peruvianus, Hylochœrus meinertzhageni meinertzhageni*! Surely "when ghost meets ghost" in the Elysian fields Linnæus will pertinently ask the newcomer, "Who is responsible for this violence to the serene simplicity of my binomial nomenclature?"

(4) "Nature and Science on the Pacific Coast," by thirty highly qualified writers, is a handbook of which it is not too much to say that quotations could agreeably and instructively fill many columns. Within a limit of fewer than 300 pages for the whole, each author has had to condense his wealth of information into the smallest possible compass. From the theory of earthquakes and the origin of petroleum to the war between benevolent bugs and pestilent scale-insects, from the history of the Panama Canal to the "influence of natural conditions upon legal and political institutions," nothing seems to have been forgotten. Geology and astronomy, flora and fauna, industries and amusements, have each their turn, with indices to literature for information beyond what can be compressed into a nutshell. Fishes receive more notice than mammals, and an extract from their record may be usefully quoted.

"Besides the trout and salmon, California has many other game fishes. First of these is the great tunny or leaping tuna, which ranges from 150 pounds to half a ton, and finds its greatest abundance about Avalon. This wonderful bay of Avalon has many other roving fishes, taken with the trolling spoon, such as the yellow-tail (*Seriola dorsalis*), the albacore (*Thunnus alalunga*), the yellow-fin, or Japanese albacore (*Thunnus macropterus*), and the huge bass called Jew-fish (*Stereolepis gigas*), with a head as large as a bushel basket—apparently nearly all head. The sword-fish (*Xiphias gladius*), and the Japanese spear-fish (*Tetrapturus mitsukurii*), are also sometimes taken off the Santa Barbara Islands.

"These noble fishes deserve protection from the amateur angler who catches a dozen or a hundred, has them hung up and photographed, himself beside them, then hires the guide to bury them while he goes away to have fun in his own fashion somewhere else."

THOMAS R. R. STEBBING.

AN ITALIAN TEXT-BOOK OF PHYSIOLOGY.

Human Physiology. By Prof. L. Luciani. Translated by F. A. Welby. Vol. iii.—Muscular and Nervous Systems. Edited by Dr. G. M. Holmes. Pp. x+667. (London: Macmillan and Co., Ltd., 1915.) Price 18*s*. net.

THE third volume of the English version of Luciani's "Human Physiology," translated from the Italian original published in 1913, deals with the general physiology of muscle, the mechanics of locomotion, phonation, and articulation, and the general and special physiology of the nervous system.

The chief characteristics of Luciani's work have already been referred to in the reviews of the first two volumes. The first chapter of the present volume gives an excellent account of the general physiology of muscle. The successive stages in the historical development of the subject are described with great clearness and unusual fullness. Although an admirable account is also given of the most recent work, further details regarding the physico-chemical theories of muscular activity might possibly have been included with advantage. Fortunately the bibliography given at the close of the chapter offers excellent guidance to students desiring fuller knowledge of the latter views. In the discussion of the nature of voluntary muscular contraction, no reference is made to the important results obtained by Piper and others with the aid of the string galvanometer. The use of the latter instrument has enabled these observers to analyse the discontinuous character of voluntary muscular contraction more accurately than was possible by means of earlier methods.

A very full and clear account of the mechanics of the locomotor apparatus is given in chapter ii. The subjects of phonation and articulation are discussed much more thoroughly in chapter iii. than in most English text-boks of physiology, and the editor has found some abridgment desirable in the interests of students.

An exceedingly interesting summary of the most recent work on the metabolism of the nervous system is given at the close of chapter iv. The remainder of the volume is devoted to the special physiology of the central nervous system, and of the sympathetic system. A brief review cannot do justice to the clearness and completeness of the presentation given by the author. The very full account of the physiology of the cerebellum has a special value as the work of one of the greatest authorities in this field.

The English rendering given by Miss Welby

shows the high qualities of lucidity and excellent literary style characteristic of her previous work. The value of the text-book for English students has been greatly enhanced by the additions to the bibliography, which have been made by the editor, Dr. Gordon Holmes. In conclusion it may be stated that the high level of excellence secured in the first two volumes has been well maintained, and leaves no doubt that the work, when completed, will be a most important and valuable addition to the English literature of physiology.

ELEMENTARY GEOGRAPHY.

(1) *A First Geography of the British Isles.* By W. M. Carey. Pp. vi+169. (London: Macmillan and Co., Ltd., 1915.) Price 1s. 6d.

(2) *Bacon's Sixpenny Contour Atlas.* North England Edition. Pp. 41. Southern Wales Edition. Pp. 41. Lancashire and Yorkshire Edition. Pp. 41. (London: G. W. Bacon and Co., Ltd., n.d.) Price 6d. net each.

(1) THIS book has been written for classes preparing for preliminary or junior local examinations of the universities; it begins by considering latitude and longitude, and the climate of Britain is not considered until the last chapter; all this means that a good deal of previous reading and learning is presupposed. There is a large amount of information, much of it interesting and "curious," and it is markedly accurate; but the comparison of particulars and progression in idea which might be expected in a volume of a "First Book of Science" series are largely absent.

Of the eleven chapters which the book contains, eight deal with the geography of as many different regions, while the two first and the last deal with Britain as a whole. An excellent feature is that each chapter is preceded by about half a dozen practical exercises, and is followed by a similar number of questions partly taken from public examinations and partly original. The practical exercises probably supply the reason why the book is included in the series; but it may be doubted whether there are not too many of the type in which the lengths of certain rivers are given in miles and the pupil is asked to draw lines to represent those lengths to scale. As a means of keeping the youngsters quiet this is good, but the geographical value of the work is small, and it does not help them to remember the relative lengths. Notwithstanding its excellent qualities, we are disappointed with the book. The impression is that there are very many facts, but important and unimportant alike appear to receive the same attention.

The index would have been more useful had it been complete; on a page taken at random nine names were indexed and a dozen were not.

With (2) on the market in its several editions, no school, however straitened, can plead that it cannot afford a satisfactory atlas because of the cost. There are few other atlases on the market which at the price are possible rivals. Each edition contains four local maps, showing communications, geology, relief and vegetation, twenty-four regional relief maps, and seven world maps. It is a pity that some of the work is rather rough; in the Lancashire and Yorkshire edition the Aire Gap is shown on one map to be all under five hundred feet, on another map a small part is shown just over five hundred feet, while in a third the greater portion is shown as more than five hundred feet.

OUR BOOKSHELF.

Citrus Fruits. By Prof. J. E. Coit. Pp. xx+520. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1915.) Price 8s. 6d. net.

THIS work is written by the professor of citriculture of the University of California, where he is also superintendent of the University Agricultural Experiment Station with regard to citrus fruits. The first chapter deals with the history and development of the citrus industry in California from the introduction of European fruit trees and vines by Spanish Jesuit missionaries about 1701, and traces the industry to the present time, recording the assistance to its upbuilding rendered by the Department of Agriculture, the University of California, and the Chambers of Commerce, which have aided by lectures, experiments, and advertisement, leading up to the practical result, namely, the shipment of 60,000 carloads of fruit in 1914.

The following chapters deal with the geography and climate of California; the botany of citrus fruits, their varieties and origins; improvement of varieties by breeding, and from "sports"; judging fruits; site and preparation for planting; cultivation, manuring, cover crops; irrigation; pruning and top-working; frost and orchard heating; picking and packing; blemishes and their prevention; manufacture of by-products (citric acid, candied fruit, etc.); marketing; cost and returns; diseases and their control; insect control and fumigation; horticultural inspection and quarantine; legislation.

Budding, even of old trees, is found more successful than grafting. Some of the best varieties of orange (Navel) and lemon (Eureka) are parthenocarpic, and can successfully be planted in large blocks, but most varieties require cross-pollination, and some varieties are found not to be congenial pollenisers.

The author considers the selection of "sports" a more likely source of valuable varieties than by hybridising and raising new sorts.

The above are a few selected facts of interest, but the book will be found interesting even in a country where the orange is not commercially grown, and invaluable where citrus fruits are a staple industry. CECIL H. HOOPER.

Lessons in Elementary Physiology. By Dr. T. H. Huxley. Enlarged and revised edition. Pp. xxiv + 604. (London: Macmillan and Co., Ltd., 1915.) Price 4*s*. 6*d*.

PROF. HUXLEY'S "Physiology" was a masterpiece; it first appeared in 1866, and since that date has been easily first among a crowd of elementary manuals. The edition which appeared before the present one was issued in 1900, and was then edited by Sir Michael Foster and Dr. Shore. It has been frequently reprinted since that date, but after a lapse of fifteen years the publishers have very rightly judged that it required revision in order to incorporate the new facts and generalisations which have been discovered in the meantime. This work has been entrusted to Mr. Joseph Barcroft, of Cambridge, and he has fulfilled his task with ability, tact, and, one may add, reverence. Although the repair has been substantial, one cannot but be struck with the fact how much of the fabric is left intact. There could be no better testimony to the thoroughness and permanence of the labours of the original builders. The main principles of physiological science remain for the most part unchanged. With some notable exceptions, recent physiological progress has been concerned with details, which are interesting enough to the researchers, but are really not essential from the elementary student's point of view. We wish the present edition every success and a continuance of usefulness. W. D. H.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Remarkable Nest of "Vespa norwegica," and Fertility of Workers of this Species.

THE following observations on a colony of *Vespa norwegica* are perhaps deserving of record. About the middle of July a relative living at East Liss, Hants, endeavoured to take for me a nest of this tree-wasp, but was forced to beat a retreat after merely bending the branch of the rhododendron to which the nest was attached. The effect of this bend was to throw the nest permanently out of its original position, and to incline the combs within it at a considerable angle to the horizontal plane in which they had, as always, been built. On July 28 the nest was successfully captured, and forwarded to me, together with such of its inmates as happened to be at home at the moment of capture. The combs were five in number; the three upper were each of about four inches in diameter; the fourth smaller and of irregular shape, there being a patch of small, misshapen cells placed obliquely on one margin. The position of the fifth comb was very remarkable; it was attached, not to the fourth, but to the third comb; and, moreover, instead of hanging parallel to the other combs, it was set at a decided angle to them, the angle being such that it lay in the true horizontal plane, from which the others had been displaced. It is thus evident that the worker wasps are able to discriminate between oblique and horizontal positions with some nicety. This fifth comb had obviously been built since the disturbance of the nest; it consisted of but twenty-five small, though regularly hexagonal cells, and it is probable that the patch of irregular cells added to the edge of the fourth comb was of similar date, and represents an attempt to regain the horizontal plane for that comb. The queen had also been affected by the disturbance of the nest, for she had laid two, and frequently three, eggs in many of the cells of the second and third combs, instead of the normal one egg only. There were no eggs in any of the cells of the oddly-placed fifth comb, nor in the patch of irregular cells on the edge of the fourth. The absence of eggs from these cells points to all workers being sterile up to the time when the nest was taken. Within the nest as I received it were several dozen drones, two workers, and the queen; the majority of the workers must have been afield when the nest was removed.

On August 24 I visited the bush whence the nest was obtained, and found that the workers had continued operations, although bereft of their queen. On the ground immediately beneath the place of the original nest they had built an irregular mass of wasp-paper round some dead twigs of heather, and in the midst of this mass, smothered in the wasp-paper wrappings, was a very small comb consisting of six badly-shaped cells, of which two contained eggs that had failed to develop and had shrivelled. But fastened to a branch about a foot above this mass was a small nest of normal shape, and of about two and a half inches diameter, such as might be expected in early summer. Worker wasps were visiting both these structures, and occasionally one would emerge from the nest and proceed direct to the mass upon the ground, or *vice versâ*; both were clearly the work of the one colony. I caught all the wasps—only thirty-seven in number—and found them to be workers without exception. Inside the suspended nest was one small, but perfectly regular comb composed of forty-four cells, thirty-three of which contained larvæ of various sizes. None of these larvæ looked healthy or well nourished, and three of the largest were dead and had turned pink. There was no queen in the nest; hence it is certain that at least one of the workers must have become parthenogenetically fertile.

It is probably not unusual for workers to become fertile in strong colonies towards the end of a favourable season; but I am not aware that such clear proof of worker fertility has hitherto been obtained, and it is certainly singular that reproductive powers should arise in the circumstances above narrated.

OSWALD H. LATTER.

Charterhouse, Godalming, September 7.

An Original Representation of the Giraffe.

AMONG the interesting reproductions of early figures that Prof. Eastman has lately presented to the readers of NATURE are two of the giraffe—one (NATURE, February 18) from Ehrenberg's memoir published in 1834, and the other (July 29) from a manuscript in the British Museum. Both these figures are attributed to Thebes; the former, from a "monument," is shown with a monkey-like animal on the back of its neck, and the latter, from a "tomb," has the monkey in

front of the neck. In both cases the giraffe faces towards the right, and there can be little doubt that they are efforts of our recent ancestors to try to copy an ancient picture.

G. A. Hoskins published his "Travels in Ethiopia" in 1835; consequently his animal figures are entitled to rank as early representations, though they were not done with zoological intent. A feature of the work is a series of colour-printed plates showing an expedition returning from the land of Punt, and among the figures appears to be the original of Prof. Eastman's giraffes. The accompanying illustration (Fig. 1), due to the skilled hand of Mr. W. Ashton, serves to show the delicate accuracy of Hoskins's copy, which must in its turn be very closely similar to the Egyptian painting. Attention may be directed to the prehensile lips, the form of the shoulders, and the tuft of hair at the end of the tail. The colouring of Hoskins's plate enhances the accuracy of the details. The giraffe is only an item, and, like the elephant in the same procession, is evidently a young animal, as it is only a little taller than the men in charge of it. The painting includes the leopard, hunting cat, ibex, dogs, cattle, and a curious bear-like animal, the portrait of which is probably as true to life as the others. Four distinct races are shown among the human figures who are carrying elephants' tusks, ostrich feathers and eggs, and skins of different kinds, as well as many other treasures from the southern lands.

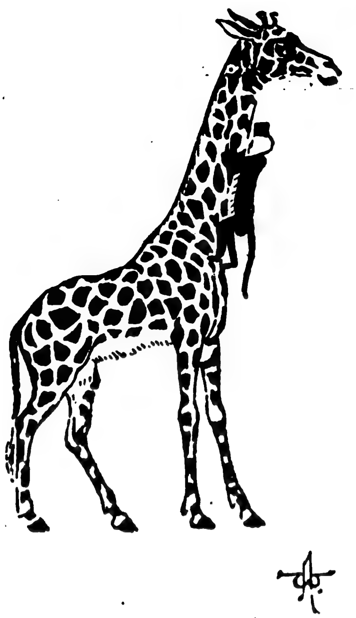

FIG. 1.—Illustration of giraffe. From Hoskins's "Travels in Ethiopia."

Hoskins states that the original painting was in a tomb of the time of Thothmes III., but excavation had not then proceeded far, and possibly the structure is what we now know to be the west terrace of Queen Hatshepset's temple of Der el Barhari. Here, according to Dr. E. A. Wallis Budge's description, there are bas-reliefs that must be very similar to, if not identical with, the painting copied by Hoskins. The expedition to Punt was a feature of Queen Hatshepset's reign, and occurred about 1600 B.C., while the association of Thothmes's name is accounted for by this gentleman's habit of substituting it for that of his predecessor.

G. W. GRABHAM.

Khartoum, August 21.

THE WORLD'S SUPPLY OF POTASH.

IN view of the scarcity of potash occasioned by the war, the Imperial Institute has issued a pamphlet (pp. 47, price 1*s*.) under the above title, in which a review is given of the existing sources of supply and suggestions made as to the possibility of obtaining potash from materials not hitherto worked for this purpose. The potash used in this country has been almost exclusively derived from the Stassfurt deposits, south of Magdeburg, which have been so systematically and economically worked since about 1862, that German potash, on account of its cheapness, has driven all other competitors from the market. Potash salts are essential constituents of plant food, and the greater part of the potash salts extracted at Stassfurt is used as a fertiliser; but relatively large quantities are employed in various chemical industries and in the manufacture of glass and soap.

Besides the Stassfurt deposits, there is only one extensive deposit of carnallite at present known, and that is the Spanish deposit of Catalonia, the working of which, it is stated, has recently been commenced. This deposit has great commercial promise, and, next to those of Stassfurt, may prove to be the most important source of potash at present known. There are also deposits in India, which may prove to be of importance if they can be worked sufficiently cheaply.

All plants contain more or less potash, and the utilisation of the ash of wood, the ash of seaweeds, of beetroot residues, and similar by-products of industries in which vegetable raw materials are employed, is of importance as a source of potash, especially at a time of scarcity like the present. The burning of seaweed and the extracting of potash from the ash, at one time an important industry on the coasts of Scotland and Ireland, has recently shown signs of revival. From Ireland during 1913, 3939 tons of kelp, valued at 16,631*l*., were exported. As a rule the Irish kelp contains more potash than that produced in Scotland. At the present time the utilisation of the giant kelps of the Pacific coast is regarded by many as the most promising source of soluble potash salts in the United States. The best account of the new industry which has sprung up on the Pacific shores was given by F. K. Cameron in a paper read before the Franklin Institute in 1913 (Journ. Franklin Institute, vol. clxxvi., p. 347). According to an official estimate 6,000,000 tons of potassium chloride could be obtained annually from this source. It was shown by Balch in 1909 that the giant algæ of the Pacific, the principal species being Nereocystis and Macrocystis, contain about five times as much potash as the majority of seaweeds, the average percentage on the dried weed being from 15 to 20 per cent. of K_2O. Since the publication of these results various labour-saving devices have been tried for cutting and collecting the weed, and the cost per ton of weed now landed is stated to be about 20 cents.

The preparation of potash salts and iodine has also become an important industry on certain parts of the coast of Japan, and it is stated that Japan now supplies about 80 per cent. of the iodine consumed in the United States. The weeds used on the coast of Japan are species of Laminaria, *Ecklonia cava, E. bicyclis,* and Sargassum, spp.

In Canada the burning of wood to ash was for several years a considerable source of potash, but

in a report recently issued by the Forestry Branch, Department of the Interior, it is stated that at the present day, owing to altered conditions, there is small possibility of reviving the potash industry as formerly practised. The amount of potash to be recovered from the waste from the sawmills is considered to be too small to be regarded as commercially practicable for the mills to undertake its recovery. In most cases the only use for the ash from sawmill burners is for the farmers in the locality to apply it directly on the land.

Experiments made at Rothamsted recently have shown that the ash of hedge cleanings, consisting of grass, weeds, and clippings, contained on the average about 11 per cent. of potash, that is to say, about as much as kainit (Russell, Journ. Board Agric., 1914, vol. xxi., p. 694). The potash is present in a very soluble form (carbonate) and is rapidly washed away. If it is to be utilised, therefore, care must be taken to protect the ashes from showers of rain while they are cooling.

A rather neglected source of potash is the soapy water used for removing grease from wool. The matter soluble in water contains potash equivalent to 5 per cent. of potassium carbonate, calculated on the raw wool, but as the recovery of potash is not remunerative unless conducted on a large scale, the wool washings are usually allowed to go to waste. On the other hand, in Belgium, France, and Germany the wool suint is utilised as a source of potash; it is estimated that in the Roubaix district alone potash salts to the value of 100,000*l.* are obtained annually from this source.

One of the most promising future sources of potash supplies seems to be the recently discovered deposits in Alsace. In 1904 deep borings were made at Niederbruck in the hope of striking oil, but instead saline matter was encountered at the depth of 1174 ft. Since then the number of mines has increased to twelve; in 1912 the output was 137,243 metric tons, and in 1913, 350,341 metric tons. Recent reports state that the Alsatian deposits are probably continued across the Rhine into Baden.

During the past few years attention has been directed to the possibility of employing as manures, with or without previous treatment, minerals which contain potash in an insoluble form; the more important of these are alunite, felspar, and leucite. An account is given in the pamphlet of the methods which have been experimented with.

W. A. D.

PROF. D. T. GWYNNE-VAUGHAN.

AFTER completing barely one year of duty in the chair of botany at Reading, Prof. Gwynne-Vaughan died on September 4. He was only forty-four years of age, but he had made a solid position for himself as a plant anatomist, and he had already shown his capacity as a teacher and a director of research. A life not only of promise, but also of notable achievement has thus come to a premature close.

Born in 1871, at Llandovery, he was educated at Monmouth School, whence he passed as scholar to Christ's College, Cambridge, and took the Natural Sciences Tripos. After graduation he held a mastership for a time, but soon relinquished it to pursue research. For this end he went to the Jodrell Laboratory, Royal Gardens, Kew, which was then under the directorship of Dr. D. H. Scott. Here his investigations of stelar morphology began, and in 1897 he published his first results on Nymphæaceæ (Trans. Linn. Soc.) and Primulaceæ (*Annals of Botany*). A peculiarly lucid preliminary statement at the British Association at Liverpool (1896) led to his appointment as assistant in botany in the University of Glasgow, where he worked for about ten years, laying the foundation of his unrivalled knowledge of the anatomy of the Pteridophyta. In 1907 he became head of the department of botany in Birkbeck College, London, but after two years he was appointed professor of Botany in Belfast. Finally, in 1914, he took up similar duties at Reading. In 1911 he married Dr. H. C. I. Fraser, herself an accomplished botanist, who had succeeded him in the post at the Birkbeck College.

He acted for several years as secretary and afterwards as recorder of the botanical section of the British Association, winning the warm regard of all its members. His funeral occurring on the opening day of its current session in Manchester, the business of the section was by common consent suspended during the time of the service.

Gwynne-Vaughan's position as an anatomist is based, not only on his published works, but also upon a great accumulation of well-assured facts recorded in notes, which he readily made available to his colleagues. He was chiefly interested in stelar problems relating to the Filicales. From the list of his works two series of papers may be mentioned as of outstanding importance. The first includes the two memoirs on solenostelic ferns (*Ann. of Bot.*, 1901, 1903), in which he established the method of representation of the vascular system in the solid, as reconstructed from sections. The second series was written in happy co-operation with Dr. Robert Kidston, and dealt with the fossil Osmundaceæ (Trans. R.S. Edin., 1907–1911). Seldom have two minds blended their results more effectively. The one brought to bear a wide knowledge of fossils from the stratigraphical and systematic point of view. The other supplied critical and expert anatomical experience, based upon study of living plants. The result is a series of beautifully illustrated memoirs, which trace in a natural sequence of plants an anatomical progression which follows most convincingly the successive stratigraphical horizons. They also indicate the underlying method of that progression which finds its reflection in other series of vascular plants. Already these memoirs may be held to have taken their place among the botanical classics.

Work of such a nature already achieved makes

the more acute the loss of Gwynne-Vaughan at a relatively early age. To his colleagues he was most loyal and helpful. His own results were always strictly tested and criticised. The consequence will be that they will be durable, and take permanent place in the web of botanical science.

F. O. B.

THE BRITISH ASSOCIATION AT MANCHESTER.

THE British Association this year was favoured with exceptionally fine weather. The sun shone all day long, and not a drop of rain interfered with the visits to works and the short sectional excursions to places of scientific interest. The number of members and associates (1438), although satisfactory in the circumstances of a great European war, was small as compared with previous meetings. From these two factors it might have been anticipated that the attendances at the sections would be unsatisfactory. But from all accounts that have been received the section rooms have been well filled both in the morning and afternoon sittings, and the proceedings have been of quite exceptional interest and importance. It is evident, therefore, that the modifications of the usual programme that were made for the Manchester meeting have affected those who attend the association for the sake of the excursions and social functions far more than those who regard it seriously as an opportunity for scientific work and exchange of ideas.

It may be a question for the serious consideration of the council whether the Manchester model (1915), as it may be called, is not one which should be followed in future meetings of the association; but it may be said, without fear of contradiction, that the decision of the local executive committee to repeat its invitation, after the declaration of war, has been fully justified.

The reception by the Lord Mayor in the School of Technology on Wednesday evening was the only general social function of the week, but being fixed on the second day of the meeting it gave a welcome opportunity to members to meet their friends as well as to inspect the machinery, appliances, and lecture-rooms with which this great institution is equipped. The arrangements made by the committee for the visits of members to factories, warehouses, municipal undertakings, and various places of special interest in Manchester and district worked well, and the short excursions were well attended. The citizens' lectures given in Manchester and other towns in the neighbourhood attracted large audiences.

The meeting may be pronounced a decided success, and the vote of thanks to the local executive committee moved by the president at the concluding meeting on Friday evening was very heartily accorded.

Next year's meeting is to be held at Newcastle, under the presidency of Sir Arthur Evans, but final arrangements will not be made until about next March. The place of meeting in 1917 is to be Bournemouth.

Subjoined is a synopsis of grants of money appropriated for scientific purposes on behalf of the general committee at the Manchester meeting just concluded. The names of members entitled to call on the general treasurer for grants are prefixed to the respective committees. Reappointed committees are starred, and it will be noticed that of the forty-one committees receiving grants, only five are new.

CONFERENCE OF DELEGATES OF CORRESPONDING SOCIETIES.

OPENING ADDRESS BY SIR THOMAS H. HOLLAND, K.C.I.E., D.Sc., F.R.S., PRESIDENT OF THE CONFERENCE.

The Organisation of Science.

AMONG the many lessons we learn in every great war, there is always one that stands out prominently as something of fundamental and national importance. In the Crimea our shortcomings in commissariat organisation were demonstrated with painful emphasis. In South Africa we learnt something of the way in which the initiative of the individual, naturally more prominent in the amateur soldier, triumphs, in unforeseen circumstances, over any system fixed by formal and traditional discipline. The great war now in progress will result more completely than any of its puny predecessors in recasting our national ideas, economic, political, and military.

Of all the lessons we are likely to learn, the one that so far promises most to affect the life of the nation may be summed up in a word, *organisation.* The fuss made lately about the shortage of munitions; the discovery in the ranks of the Army and among its officers of thousands who are only amateur fighters but are professionally trained technologists; the recasting of the Cabinet; the introduction, twelve months after the commencement of the war, of legislation to register and classify the technical qualifications of the people; the repeated occurrence of coal strikes on a large scale, settled only by the intervention of Cabinet Ministers, and by an obviously temporary compromise, are all confessions of our shortcomings in national organisation—shortcomings that have already cost the country thousands of lives.

On the other side of the "front" we see organisation raised to the level of a national cult—*Kultur*—with the result that, while efficiency in action and economy in the utilisation of a country's resources have been raised to a standard hitherto unknown, and by us undreamt of, the human instincts have been drilled out of existence, and Germany stands alone as an almost perfect machine in action, but, like a machine, unable to understand the rest of the human race; admired for its mechanical efficiency, but loathed for its degradation of the great human instincts of liberty and toleration.

But between these extremes there must be a course of maximum wisdom; for admittedly both the organisation of the community (the feature which is supposed to dominate the professional classes) and freedom of the individual (the prerogative of the amateur) are necessary for the progress of what is best in civilisation.

Every meeting of the British Association reminds us that early in the last century a body of learned men realised that the form of study popularly known as scientific needed organising, required the strengthening influence of a protective guild—the formation of a cult—in order that its value might be forced on the popular mind. Long before the foundation of the British Association a comparatively small number of men had interested themselves in scientific problems, and their work had so far progressed as to require specialisation, with the foundation of distinct societies. This specialisation found expression at the first three meetings of the association by the formation of committees for (i) Mathematics and General Physics; (ii) Chemistry and Mineralogy; (iii) Geology and Geography; (iv) Zoology and Botany; (v) Anatomy and Physiology; and (vi) Statistics.

These six groups have developed into our present twelve sections and extra subsections, and in practice every section, by classification of its papers and in the conduct of its discussions, acknowledges a further specialisation that is none the less real because it has not been yet formally recognised in organisation.

It is difficult for us to realise that, although the collection of scientific data and thought had made such progress eighty-four years ago as to require the subdivision indicated by the first institution of the British Association, the importance of science was still scarcely recognised among the so-called learned and ruling classes. Obvious if insufficient progress had been made since the days when it was possible for Dean Swift to issue, as tolerable literature, his satires on the Royal Society, or for Robert South to add to his doubtful popularity by describing its members as incapable of admiring anything except "fleas, lice, and themselves."

Although science now takes its place on equal terms with literature in the world of academic culture, we have so far succeeded only to a very small extent in getting the professors of pure science to co-operate in unison with the captains of industry who depend entirely, consciously or otherwise, on the application of scientific laws to industrial problems.

There has hitherto been a tendency for scientific and literary men to gather together under one banner, with the motto "learned," but a more natural association should be indicated by the community of interests between scientific men and technical experts. The student of pure science often discovers laws or formulates theories which are but accidentally carried beyond the purely intellectual world. On the other hand, technical experts frequently work by empirical methods that are discovered either by accident or as

the result of many costly blunders. The growth of science and of commercial technology has been largely independent and unrelated, that is, without organisation.

The absence of this organisation has shown itself for many years to those who are able to read the signs of the times, by the way in which German applied science has assisted commercial activity in trespassing on markets created and formerly occupied by British enterprise. The result of organised co-operation on one hand and of disconnected effort on the other, has now been brought home to us all, suddenly and painfully, by the war. In the utilisation of technical science the German army has had an enormous advantage for which we have had to pay by the lives of some of our best officers and men.

In Germany the scientific, technical, and commercial community (not communities) is mobilised, and each individual in it has been given his appropriate function. In this country, on the other hand, we still have endless instances of right men in wrong places, while scientific activity seems to be devoted to the voluntary formation of innumerable and often irresponsible committees, with overlapping functions and with no apparent common aim in view. Nothing could more clearly demonstrate our shortcomings in organisation than the columns of the daily Press, which are filled with complaints from scientific men who, though among the most distinguished in the world of pure science, are, in this great struggle, still unemployed, and unfortunately often show by the tone of their complaints that they are also unemployable.

A small fraction of the time now devoted in this country to discussion in committee would be sufficient, if turned to well-directed effort, to remove many of the handicaps from which our Navy and Army are now suffering in this critical stage of the war. Most committees might be justifiably likened to two athletes at the east end of a church, discussing the better route by which to get around to the tower, while a cripple starts off at once by one of the routes (possibly even by the less easy of the two); yet the cripple gets there while the athletes are still wrangling.

The root trouble with us is due to the fact that our committees are generally composed of members appointed, not because they are the best able to solve the problem in hand, but because they represent vested interests, and vested interests have now grown to dimensions beyond power of removal, because our institutions are often the products of worthy local, unconnected and therefore unorganised, effort. In their relations to one another, institutions that profess a common public aim show a spirit of jealous competition more prominently than any community of ideal. One cannot study the recent history of university education in London without being painfully impressed with the fact that internal friction in a machine without design results in a consumption of energy that costs more than the educational output is worth.

Our scientific and technical societies similarly suffer from overlapping and conflicting interests, and this conference will be of some value if, instead of discussing for once some special scientific problem, its members become inspired with a desire to direct the activities of the societies they represent so as to reduce the quantity of machinery; to correlate their activities with those of the metropolitan institutions with headquarters in London; to subdivide those institutions composed of dissimilar elements, and to assist, so far as practicable, the regrouping of those who work with common data and with a common aim.

An excellent illustration exists of the way in which reform of this kind is possible when members are sufficiently public-spirited to distinguish between the wider interests of science and those of their own special societies. Up to 1889 there were in this country about eight separate societies devoted to the technical interests mainly of coal mining. In that year four of these societies federated their interests, and during the few following years three others joined the federation and pooled their resources to meet the cost of a common publication and to maintain a common office at Newcastle.

In 1892 the Institution of Mining and Metallurgy was founded in London to meet the wants of technologists devoted mainly to the requirements of metalliferous mining. The rapid growth of this institution, its metropolitan location, and its comprehensive name, challenged the premier position of the Federated Institution of Mining Engineers. The latter consequently changed its name to *The* Institution of Mining Engineers, and moved its central office to London. Thenceforward each institution, not only published papers on its own special branch of mining, but trespassed frequently on the natural domains of its competitor. Later, when one of these institutions applied for a Royal Charter, the other in its own interests successfully opposed the application.

But in 1913, through the happy possession of two presidents who could distinguish parochial from national interests, both institutions agreed to a delimitation of their spheres of influence, and each supported with success the petition of the other for a Royal Charter. They are now no longer competitors, but sister institutions, and, instead of competing for recruits, they can afford to define and maintain a high standard of technical qualification and professional etiquette for the British mining engineer.

One of the first principles observed by a student of science is that of classification. Classification means not merely the bringing together of things that are similar in some essential feature; it also means the separation of those that are essentially unlike, although superficially bearing some form of resemblance.

One realises how hard it is to apply the pruning knife of scientific classification when one contemplates the spectacle of various "literary and philosophical societies" which still survive, mostly under financial difficulties, in many of our large provincial cities, vainly endeavouring to cover "the whole realm of nature." Such societies, embracing the general range of sciences, and sometimes even including literary subjects, exist at Aberdeen (founded in 1840), Birmingham (1858), Cambridge (1819), Edinburgh (1731), Glasgow (1802), Hull (1823), Leeds (1820), Manchester (1781), Newcastle (1793), and York (1822), while at Dublin, where individuality seems ever to flourish in various departments of civilised activity, there are two such societies with, apparently, partly overlapping interests in general science—the Royal Dublin Society, founded in 1731, and the Royal Irish Academy, founded in 1785.

There are not many among these societies the publications of which can be safely neglected by the research worker in any of the specialised branches of science, and yet most of them could not show an average annual output of one serious paper in each of the science subjects as defined by the twelve sections of the British Association. They become in turn the fortunate victims of some local enthusiast, who, in time, passes away like a comet or finds wider scope for his ambitions, either in the Royal Society of London or in the metropolitan society that governs his own pet subject, where his products enjoy the benefit of more thorough discussion, often with appreciation, by fellow-experts.

If we take the Literary and Philosophical Society of this city (which for many years has devoted itself almost entirely to science, and issues memoirs which

no serious worker can afford to overlook) we get an example of the way in which the student is taxed in his search for the "previous literature." Of ninety-one papers published in the Manchester Memoirs during the past five years as many as thirty-four belong to a class that would be referred to Section A of this association, this abundant enthusiasm being largely due to a local occurrence of radio-activity. Of the remainder ten would come under Section B, seven, entirely palæontological in character, come under Section C, twenty-two under D, two under H, two under I, thirteen under K, and one under M.

One can sympathise with those readers who grumble at the one halfpenny-worth of geological bread to this intolerable deal of physical and biological sack.

Now, it is important to remember that this society is maintained by fewer than 150 members, many of whom are members only through general interest in science or merely in consequence of a commendable desire to keep alive an institution which has an honourable record. The critical discussion of most papers presented must therefore be confined to a very small number, and herein arises a danger that may at any time give rise to consequences far more serious than the burial of a paper with an overburden of unrelated literature; for the author of the paper himself must often be the only member capable of deciding as to whether his paper is or is not suitable for record as a definite addition to scientific data or thought.

To the outside student, therefore, the publication of a paper by such a small society gives no *prima facie* reason for regarding it as a serious and probably trustworthy addition to scientific literature. The papers so issued must be most embarrassingly unequal and wholly indeterminate in character; yet no stranger can run the risk of disregarding such publications.

But the tax thus laid on students of scientific literature is not the only drawback or danger due to the activities of such small local non-specialised societies. They often possess collections of natural history specimens or of physical instruments for which they become, by mere possession, trustees to the whole scientific world. As in the case of published literature, the circumstance that these things are often unknown to the rest of the world or are almost inaccessible to the student is only one and not the most serious danger; for one knows instances of collections suffering from neglect, or, still worse, suffering from the activities of some member who temporarily dominates the governing body, and entertains strong views as to the cost of maintaining collections that, from his special point of view, are of no value.

Before proposing, in the name of organisation, to abolish such unspecialised societies, or before even suggesting that they might be allowed to die a natural death, one should exert one's ingenuity to devise some scheme for turning them to account. They inherit traditions in most cases that only an unregenerate iconoclast would despise; most of them were founded when science was barely specialised, and when facilities for attending London meetings were imperfect; many of them have published memoirs that are now of classical value, and have included among their active members the most worthy names in the history of science; most of them possess libraries that could not now be purchased for money, although these are often neglected, and, for financial reasons, often difficult to use.

Even as monuments, therefore, societies such as those that I have mentioned deserve preservation. How, then, can one turn their resources to good account and organise their culture without the drawbacks of *Kultur?*

The plan that has often occurred to me as a possible compromise between the claims of central organisation and provincial autonomy is this. The recognised chief among such societies—the Royal Society of London—should, by affiliation of its provincial poor relations, take over the cost as well as the responsibility of their serious publications. They would enjoy home rule so far as their meetings, discussions, finances, and libraries are concerned; but the papers offered for publication would be censored in the usual way by the appropriate sectional committees of the Royal Society, and, if passed, would be published, either in the Proceedings and Transactions of the Royal or of some metropolitan specialised society. Such papers would then rank technically, not by mere courtesy, as "publications" for purposes of quotation or priority. The local interest in science would not then be curtailed, and the geographical handicap, especially felt by junior provincial workers, would be removed, while the provincial scientific communities would be able to maintain their treasured monuments, without, as now, a constant fear of financial difficulties, and without a recurring dread that senility in the respected old "lit. and phil." will soon end in the way of all things living.

So far as our local example is concerned, many, if not most, of the papers which I have just classified by the B.A. system might well have been accepted by the Royal Society, for the majority of the papers published in its Proceedings are also by non-members. The last six volumes of the Proceedings of the Royal Society contain papers by 384 authors, of whom only 141 are fellows of the society.

I am quite aware of many difficulties in the way of this proposal—fears on the one side that the council of the Royal Society will acquire a dangerous power of controlling the freedom of the scientific writer, and forebodings on the other that the duties of the council threaten to become "heavy burdens and grievous to be borne," while the cost of such additional publications will be removed from the local body only to be thrust upon the Royal Society.

The circumstance that a young worker's paper has been hall-marked by the Royal Society will soon be regarded as fair compensation for what would, after all, be but partial loss of freedom; for the local societies, as well as the various journals, can still publish what they like, though the foreign student may not be blamed for neglecting any but technically published scientific literature.

The extra burdens added to the council and sectional committees of the Royal Society are merely of a kind that someone *must* undertake if we are to have any regard at all for the progress of science, and it will soon be necessary for the State to recognise the national value of the work done by the council and committees of the Royal Society in more ways than nominal recognition of their ornamental positions. In practically every country on the continent of Europe the premier learned academies that occupy positions corresponding to the Royal Society of London are financially supported by the State, and even the ordinary members are paid.

In this country scientific organisations, like the universities, are largely dependent on private charity, with the result that, while we get the benefits of individuality and local competition, we suffer, as the war has already proved to us, the necessary loss of power due to an undesirable number of wheels in our machine, due to unnecessary duplication of effort, and due to industrial and financial eddies in the stream of progress; in a word, due to want of method and organisation. That is the theme which I wish the delegates present to take back for practical consideration by the societies that we represent.

It is important to remember that organisation necessarily requires someone to take the lead and someone to fill the subordinate's place; otherwise, all is anarchy, and whatever may be the discipline within each society, their relations to one another at present can but be described as anarchy; the fellow of the Royal Society has no more responsibility at present than any member of the smallest debating club; his selection is regarded as an honour, but an honour is as meaningless as an iron cross if it does not imply responsibility and an opportunity for more work. What applies to an individual applies to a society of such persons. The premier position of the Royal Society is acknowledged by every British worker in science, and those societies which similarly embrace all phases of science can assist the aims of organisation by reminding the Royal Society that its position is more than ornamental, and that its lead will be welcomed.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY PROF. W. M. BAYLISS, M.A., D.SC., F.R.S., PRESIDENT OF THE SECTION.

The Physiological Importance of Phase Boundaries.

EVEN a hasty consideration of the arrangements present in living cells is sufficient to bring conviction that the physical and chemical systems concerned operate under conditions very different from those of reactions taking place between substances in true solution. We become aware of the fact that there are numerous constituents of the cell which do not mix with one another. In other words, the cell system is one of many "phases," to use the expression introduced by Willard Gibbs.

Further, parts of this system which appear homogeneous under the ordinary microscope are shown by the ultra-microscope to be themselves heterogeneous. These are in what is known as the colloidal state. Some dispute has taken place as to whether this state is properly to be called a heterogeneous one, but it is sufficient for our purpose to note that investigation shows that the interfaces of contact between the components of such systems are the seat of the various forms of energy which we meet with in the case of systems obviously consisting of phases which can be separated mechanically, so that considerations applying to coarsely heterogeneous systems apply also to colloidal systems. Although the phases of a colloidal system cannot be so obviously and easily separated as those of an ordinary heterogeneous one, this can be done almost completely by filtration through membranes such as the gelatin in Martin's process. To avoid confusion, however, it has been suggested that the colloidal state should be spoken of as "micro-heterogeneous." There are, in fact, certain phenomena more or less peculiar to the colloidal state and due to the influence of the sharp curvature of the surfaces of the minutely subdivided phase. The effect of this curvature is a considerable pressure in the interior of the phase, owing to the surface tension, and it adds further complexity to the properties manifested by it.

We see, then, that the chemical reactions of chief importance to us as physiologists are those known as "heterogeneous." This class of reactions, until comparatively recent times, has been somewhat neglected by the pure chemist.

In some of its aspects, the problem before us was discussed by one of my predecessors, Prof. Hopkins, as also by Prof. Macallum, but its importance will, I think, warrant my asking your indulgence for a further brief discussion. Permit me first to apologise for what may seem to some of those present to be an unnecessarily elementary treatment of certain points.

It is easy to realise that the molecules which are situated at the interface where two phases are in contact are subject to forces differing from those to which the molecules in the interior of either phase are subject. Consider one phase only, the molecules at its surface are exposed on the one side to the influence of similar molecules; on the other side, they are exposed to the influence of molecules of a nature chemically unlike their own or in a different physical state of aggregation. The result of such asymmetric forces is that the phase boundary is the seat of various forms of energy not present in the interior of the phase. The most obvious of these is the surface energy due to the state of tension existing where a liquid or a gas forms one of the phases. It would lead us too far to discuss the mode of origin of this surface tension, except to call to mind that it is due to the attractive force of the molecules for one another, a force which is left partially unbalanced at the surface, so that the molecules here are pulled inwards. The tension is, of course, only the intensity factor of the surface energy, the capacity factor being the area of the surface. We see at once that any influence which alters the area of the surface alters also the magnitude of that form of energy of which we are speaking.

This is not the only way in which the properties of substances are changed at phase boundaries. The compressibility of a solvent, such as water, are altered, so that the solubilities of various substances in it are not the same as in the interior of the liquid phase. It is stated by J. J. Thomson that potassium sulphate is 60 per cent. more soluble in the surface film. The ways in which the properties of a solvent are changed are sometimes spoken of as "lyotropic," and they play an important part in the behaviour of colloids. We meet also with the presence of electrical charges, of positive or negative sign. These are due, as a rule, to electrolytic dissociation of the surface of one phase, in which the one ion, owing to its insolubility, remains fixed at the surface, while the opposite ion, although soluble, cannot wander away further than permitted by electrostatic attraction. Thus we have a Helmholtz double layer produced.

Before we pass on to consider how these phenomena intervene in physiological processes, there is one fact that should be referred to on account of its significance in connection with the contractile force of muscle. Surface tension is found to *decrease* as the temperature rises, or, as it is sometimes put, it has a negative temperature coefficient. This is unusual; but, if we remember that the interface between a liquid and its vapour disappears when the temperature rises to the critical point, and with it, of course, all phenomena at the boundary surface, the fact is not surprising that there is a diminution of these phenomena as the critical temperature is approached.

Perhaps that result of surface energy known as "adsorption" is the one in which the conditions present at phase boundaries make themselves most frequently obvious. Since the name has been used somewhat loosely, it is a matter of some consequence to have clear ideas of what is meant when it is made use of. Unless it is used to describe a definite fact, it can only be mischievous to the progress of science.

Permit me, then, first to remind you of that fact of universal experience, known as the "dissipation of energy," which is involved in the second law of energetics. Free energy—that is, energy which can be used for the performance of useful work—is in-

variably found to diminish, if the conditions are such that this is possible. If we have, therefore, a system in which, by any change of distribution of the constituents, free energy can be decreased, such a change of distribution will take place. This is one form of the well-known "Principle of Carnot and Clausius."

Now, practically any substance dissolved in water lowers the surface tension present at the interface between the liquid and another solid or liquid phase with which it is in contact. Moreover, up to a certain limit, the magnitude of this effect is in proportion to the concentration of the solute. Therefore, as was first pointed out by Willard Gibbs, concentration of a solute at an interface has the effect of reducing free energy and will therefore occur. This is adsorption. As an example, we may take the deposition of a dye-stuff on the surface of charcoal, from which it can be removed again, unaltered, by appropriate means, such as extraction with alcohol. Charcoal plus dye may, if any satisfaction is derived from the statement, be called a compound. But, since its chemical composition depends on the concentration of the solution in which it was formed, it is much more accurate to qualify the statement by calling it an "adsorption-compound." Moreover, the suggestion that the union is a chemical one tends to deprive the conception of chemical combination of its characteristic quality, namely, the change of properties. Dye-stuff and charcoal are chemically unchanged by adsorption.

The origin of adsorption from surface tension is easily able to explain why it is less as the temperature rises, as we find experimentally. As we have just seen, surface tension diminishes with increase of temperature.

Let us next consider what will happen if the liquid phase contains in solution a substance which lowers surface tension and is also capable of entering into chemical reaction with the material of which the other, solid, phase consists. For example, a solution of caproic acid in contact with particles of aluminium hydroxide. On the surface of the solid, the concentration of the acid will be increased by adsorption, and, in consequence, the rate of the reaction with it will be raised, according to the law of mass action. Further, suppose that the liquid phase contains two substances which react slowly with each other, but not with the solid phase. They will be brought into intimate contact with each other on the surface of the solid phase, their concentration raised and the rate of their interaction increased. One of the reagents may clearly be the solvent itself. But in all these cases the rate of the reaction cannot be expressed by a simple application of the law of mass action, since the active masses are not functions of the molecular concentrations, but of the surface of the phase boundaries. The application of these considerations to the problem of the action of enzymes and of heterogeneous catalysis in general will be apparent. That the action of enzymes is exerted by their surfaces is shown, apart from the fact that they are in colloidal solution, by the results of experiments made in liquids in which the enzymes themselves are insoluble in the usual sense, so that they can be filtered off by ordinary filter paper and the filtrate found to be free from enzyme. Notwithstanding this insolubility, enzymes are still active in these liquids. The statement has been found, up to the present, to apply to lipase, emulsin, and urease, probably to trypsin, and the only difficulty in extending it to all enzymes is that of finding a substrate soluble in some liquid in which the enzyme itself is not. That adsorption is a controlling factor in the velocity of enzyme action has been advocated by myself for some years, but it is not to be understood as implying that the whole action of enzymes is an "adsorption phenomenon," whatever may be the meaning of this statement. The rate at which the chemical reaction proceeds is controlled by the mass of the reagents concentrated on the surface of the enzyme phase at any given moment, but the temperature coefficient will, of course, be that of a chemical reaction.

The thought naturally suggests itself, may not the adsorption of the reacting substances on the surface of the enzyme suffice in itself to bring about the equilibrium at a greater rate, so that the assumption of a secondary chemical combination of a chemical nature between enzyme and substrate may be superfluous? I should hesitate somewhat to propose this hypothesis for serious consideration were it not that it was given by Faraday as the explanation of one of the most familiar cases of heterogeneous catalysis, namely, the union of oxygen and hydrogen gases by means of the surfaces of platinum and other substances. The insight shown by Faraday into the nature of the phenomena with which he was concerned is well known and has often caused astonishment. Now, this case of oxygen and hydrogen gases is clearly one of those called "catalytic" by Berzelius. The fact that the agent responsible for the effect did not itself suffer change was clear to Faraday. I would also, in parenthesis, direct attention to the fact that he correctly recognised the gold solutions which he prepared as suspensions of metallic particles—that is, as what we now call colloidal solutions. Although the systematic investigation of colloids, and the name itself, were due to Graham, some of the credit of the discovery should be given to the man who first saw what was their nature. Adsorption, again, was accurately described by Faraday, but without giving it a name.

I confess that there are, at present, difficulties in the way of accepting concentration by adsorption as a complete explanation of the catalytic activities of enzymes. It is not obvious, for example, why the same enzyme should not be able to hydrolyse both maltose and saccharose, as it is usually expressed. Another difficulty is that it is necessary to assume that the relative concentration of the components of the chemical system must be the same on the surface of the enzyme as it is in the body of the solution; in other words, the adsorption of each must be the same function of its concentration. Unless this were so, the equilibrium position on the enzyme surfaces, and therefore in the body of the solution, would be a different one under the action of an enzyme from that arrived at spontaneously or brought about by a homogeneous catalyst such as acid. This consideration was brought to my notice by Prof. Hopkins, and requires experimental investigation. We know, indeed, that in some cases there is such a difference in the position of the equilibrium position, for which various explanations have been suggested. But it would be a matter of some interest to know whether this difference has any relation to different degrees of adsorption of the components of the system.

At the same time, adsorption is under the control of so many factors, surface tension, electrical charge, and so on, that the possibilities seem innumerable. There are, moreover, two considerations to which I may be allowed to direct your attention. Hardy has pointed out that it is probable that the increased rate of reaction at the interface between phases may be due, not merely to increased concentration as such, but that in the act of concentration itself molecular forces may be brought into play which result in a rise in chemical potential of the reacting substances. In the second place, Barger has shown that the adsorption of iodine by certain organic compounds is clearly related to the chemical composition of the surfaces of these substances, but that this relationship does not result in

chemical combination or in abolition of the essential nature of the process as an adsorption. It would appear that those properties of the surface, such as electric charge and so on, which control the degree of adsorption, are dependent on the chemical nature of the surface. This dependence need not cause us any surprise, since the physical properties of a substance, inclusive of surface tension, are so closely related to its chemical composition.

There is one practical conclusion to be derived from the facts already known with regard to enzymes. This is, that any simple application of the law of mass action cannot lead to a correct mathematical expression for the rate of reaction, although attempts of this kind have been made, as by Van Slyke. The rate must be proportional to the amount of substrate adsorbed, and this, again, is a function both of the concentration of the substrate and of that of the products. It is, then, a continuously varying quantity. Expressed mathematically, the differential equation for the velocity must be something of this kind:—

$$\frac{dC}{dt} = KC^n$$

where n itself is an unknown function of C, the concentration of the substrate or products.

The hypothesis of control by adsorption gives a simple explanation of the exponential ratio between the concentration of the enzyme and its activity, which is found to be different numerically according to the stage of the reaction. At the beginning, it may be nearly unity; in the middle it is more nearly 0·5, as in the so-called 'square root law' of Schütz and Borissov, which is, however, merely an approximation. Simple explanations are also given of the fact that increasing the concentration of the substrate above a certain value no longer causes an increased rate of reaction. This is clearly because the active surface is saturated. Again, the effect of antiseptics and other substances which, by their great surface activity, obtain possession of the enzyme surfaces, and thereby exclude to a greater or less degree the adsorption of the substrate, receives a reasonable account. In many cases, the depressant or favouring action of electrolytes, including acid and alkali, is probably due to aggregation or dispersion of the colloidal particles of the enzyme, with decrease or increase of their total surface. It is to be noted that such explanations are independent of any possible formation of an intermediate compound between enzyme and substrate, *after* adsorption has taken place.

There is a further way in which adsorption plays a part in the chemical processes of cells, including those under the influence of catalysts. It is a familiar fact that the concentration of water plays a large part in the position of equilibrium attained in reversible reactions of hydrolysis and synthesis. A synthetic process is brought about by diminution of the effective concentration of water. There are, doubtless, means of doing this in the elaborate mechanisms of cell life, and, in all probability, it is by adsorption on surfaces, which are able to change their "affinity" for water.

I pass on to consider briefly some other cases in which the phenomena at phase boundaries require attention.

Let us turn our gaze from the interior of the cell to the outer surface, at which it is in contact with the surrounding medium. From the nature of adsorption there can be no doubt that, if the cell or the surrounding liquid contains substances which decrease surface energy of any form, these constituents will be concentrated at the interface. There are many such substances to be found in cells, some of lipoid nature, some proteins, and so on. Further, the experiments of Ramsden have shown that a large number of substances are deposited in surface films in a more or less rigid or solidified form. We are thus led to inquire whether these phenomena do not account for the existence of the cell membrane, about which so much discussion has taken place. We find experimentally that there are facts which show that this membrane, under ordinary resting conditions, is impermeable to most crystalloids, including inorganic salts, acids, and bases. There is no other explanation of the fact that the salts present in cells are not only in different concentration inside from that outside, but that there may be absence of certain salts from one which are present in the other, as, for example, sodium in the plasma of the rabbit not in the corpuscles. Moreover, the experiments of Hoeber have shown that electrolytes are free in the cells, so that they are not prevented from diffusion by being fixed in any way. The mere assumption of a membrane impermeable to colloids only will not account for the facts, since, as I have shown in another place, this would only explain differences of concentration, but not of composition. The surface concentration of cell constituents readily accounts for the changes of permeability occurring in functional activity, since it depends on the nature of the cell protoplasm, and chemical changes of many and various kinds occur in this system. If such be the nature of the cell membrane, it is evident that we are not justified in expecting to find it composed of lipoid or of protein alone. It must have a very complex composition, varying with the physiological state of the cell. Indeed, complex artificial membranes have been prepared having properties very similar to that of the cell.

This view that the membrane is formed by surface condensation of constituents of the cell readily accounts for the changes of permeability occurring in functional activity, since its composition depends on that of the cell protoplasm, and chemical changes of various kinds take place in this system, as it is scarcely necessary to remind you. In fact, the cell membrane is not to be regarded as an independent entity, but as a working partner, as it were, in the business of the life of the cell. In the state of excitation, for example, there is satisfactory evidence that the cell membrane loses its character of semi-permeability to electrolytes, etc. This statement has been shown to apply to muscle, nerve, gland cells, and the excitable tissues of plants, as well as to unicellular organisms. We shall see presently how this fact gives a simple explanation of the electrical changes associated with the state of activity.

If, then, the cell membrane is a part of the cell system as a whole, it is not surprising to find that substances can affect profoundly, although reversibly, the activities of the cell, even when they are unable to pass beyond the outer surface. The state of dynamic equilibrium between the cell membrane and the rest of the cell system is naturally affected by such means, since the changes in the one component involve compensating ones in the other. Interesting examples of such actions are numerous. I may mention the effect of calcium ions on the heart muscle, the effect of sodium hydroxide on oxidation in the eggs of the sea-urchin, and that of acids on the contraction of the jelly-fish. Somewhat puzzling are those cases in which drugs, such as pilocarpine and muscarine, act only during their passage through the membrane and lose their effect when their concentration has become equal inside and outside the cell.

The work of Dale on anaphylaxis leads him to the conclusion that the phenomena shown by sensitised plain muscle can most reasonably be explained by colloidal interaction on the surface of the fibres. The

result of this is increased permeability and excitation resulting therefrom.

I referred previously to the electrical change in excitable tissues and its relation to the cell membrane. It was, I believe, first pointed out by Ostwald and confirmed by many subsequent investigators, that in order that a membrane may be impermeable to a salt it is not a necessary condition that it shall be impermeable to both the ions into which this salt is electrolytically dissociated. If impermeable to one only of these ions, the other, diffusible, ion cannot pass out beyond the point at which the osmotic pressure due to its kinetic energy balances the electrostatic attraction of the oppositely charged ion, which is imprisoned. There is a Helmholtz double layer formed at the membrane, the outside having a charge of the sign of the diffusible ions, the inside that of the other ions. Now, suppose that we lead off from two places on the surface of a cell having a membrane with such properties to some instrument capable of detecting differences of electrical potential. It will be clear that we shall obtain no indication of the presence of the electrical charge, because the two points are equipotential, and we cannot get at the interior of the cell without destroying its structure. But if excitation means increased permeability, the double layer will disappear at an excited spot owing to indiscriminate mixing of both kinds of ions, and we are then practically leading off from the interior of the cell, that is, from the internal component of the double layer, while the unexcited spot is still led off from the outer component. The two contacts are no longer equipotential. Since we find experimentally that a point at rest is electrically positive to an excited one, the outer component must be positive, or the membrane is permeable to certain cations, impermeable to the corresponding anions. Any action on the cell such as would make the membrane permeable, injury, certain chemical agents, and so on, would have the same effect as the state of excitation. If we may assume the possibility of degrees of permeability, the state of inhibition might be produced by *decrease* of permeability of the membrane of a cell, which was previously in a state of excitation owing to some influence inherent in the cell itself or coming from the outside. This manner of accounting for the electromotive changes in cells is practically the same as that given by Bernstein.

It will be found of interest to apply to secretory cells the facts to which I have directed your attention. If we suppose that the setting into play of such cells is associated with the production of some osmotically active substance, together with abolition of the state of semi-permeability of the membrane covering the ends of the cells in relation with the lumen of the alveolus of the gland, it is plain that water would be taken up from the lymph spaces and capillaries and escape to the duct, carrying with it the secretory products of the cells. This process would be continuous so long as osmotically active substances were formed. Such a process has been shown by Lepeshkin to occur in plants, and we have also evidence of increased permeability during secretory activity in the gland cells of animals. From what has been said previously, it is evident that electrical differences would show themselves between the permeable and semi-permeable ends of such cells, as has been found to be the case.

As a modifiable structure, we see the importance of such a membrane as that described if it takes part in the formation of the synapse between neurones. The manifold possibilities of allowing passage to states of excitation or inhibition and of being affected by drugs will be obvious without further elaboration on my part.

Enough has already been said, I think, to show the innumerable ways in which phenomena at phase boundaries intervene in physiological events. Indeed, there are very few of these, if any, in which some component or other is not controlled by the action of surfaces of contact. But there is one especially important case to which I may be allowed to devote a few words in conclusion. I refer to the contractile process of muscle. It has become clear, chiefly through the work of Fletcher, Hopkins, and A. V. Hill, that what is usually called muscular contraction consists of two parts. Starting from the resting muscle, we find that it must have a store of potential energy, since we can make it do work when stimulated. After being used in this way, the store must be replenished, since energy cannot be obtained from nothing. This restoration process is effected by an independent oxidation reaction, in which carbohydrate is burnt up with the setting free of energy which is made use of to restore the muscle to its original state. Confining our attention for the moment to the initial, contractile, stage, the essential fact is the production of a certain amount of energy of tension, which can either be used for the performance of external work or be allowed to become degraded to heat in the muscle itself. It was Blix who first propounded the view that the amount of this energy of tension is related to the magnitude of certain surfaces in the muscle fibres. But the fact was demonstrated in a systematic and quantitative manner by A. V. Hill. He showed, in fact, that the amount of energy set free in the contractile process is directly related to the length of muscle fibres during the development of the state of tension. In other words, the process is a surface phenomenon, not one of volume, and is directly proportional to the area of certain surfaces arranged longitudinally in the muscle. This same relationship has been shown by Patterson and Starling to hold for the ventricular contraction of the mammalian heart and by Kosawa for that of the cold-blooded vertebrate. It appears that all the phenomena connected with the output of blood by the heart can be satisfactorily explained by the hypothesis that the energy of the contraction is regulated by the *length* of the ventricular fibres during the period of development of the contractile stress. The degree of filling at the moment of contraction is thus the determining factor.

That surface tension itself may be responsible for the energy given off in muscular contraction was first suggested by Fitzgerald in 1878, and it seems, from calculations made, that changes at the contact surface of the fibrillæ with the sarcoplasm may be capable of affording a sufficient amount. The difficulties in deciding the question are great, but, in addition to the facts mentioned, there is other interesting evidence at hand. It has been shown, by Gad and Heymans, by Bernstein and others, that the contractile stress produced by a stimulus has a negative temperature coefficient. Within the limits of temperature between which the muscle can be regarded as normal, this stress is the greater the lower the temperature. The same statement was shown by Weizsäcker (working with A. V. Hill) to hold for the heat developed in the contractile stage. Now, of all the forms of energy possibly concerned, that associated with phase boundaries is the only one with a negative temperature coefficient. Another aspect of this relation to temperature is the well-known increase of the tonus of smooth muscle with fall in temperature.

It is tempting to bring into relation with the change in surface tension the production of lactic acid. In fact, this idea was put into a definite statement by Haber and Klemensievich in 1909 in a frequently quoted paper on the forces present at phase boundaries.

The production of acid is stated to alter the electrical forces at this situation. This electrical charge involves a change of surface tension, and it is this change of surface tension which brings about the mechanical deformation of the muscle. Mines also has brought forward good evidence that the production of lactic acid is responsible for the change of tension. As to how the lactic acid is set free, and of what nature the system of high potential present in muscle may be, we require much more information. The absence of evolution of carbon dioxide when oxygen is not present shows that no oxidation takes place in the development of tension. There are other difficulties also in supposing that this system present in resting muscle is of a chemical nature. If the energy afforded by the oxidation of carbohydrate in the recovery stage is utilised for the formation of another chemical system with high energy content, the theory of coupled reactions indicates that there must be some component common to both systems. It is difficult to see what component of the muscle system could satisfy the conditions required. On the whole, some kind of system of a more physical nature seems the most probable. If it be correct that the oxidation of substances other than carbohydrate, fat, for example, can afford the chemical energy for muscular contraction, as appears from the results of metabolism experiments, a further difficulty arises in respect to a coupled reaction. But the question still awaits investigation.

On the whole, I think that we may conclude that more study of the phenomena at phase boundaries will throw light on many problems still obscure. It would probably not be going too far to say that the peculiarities of the phenomena called "vital" are due to the fact that they are manifestations of interchange of energy between the phases of heterogeneous systems. It was Clerk Maxwell who compared the transactions of the material universe to mercantile operations in which so much credit is transferred from one place to another, energy being the representative of credit. There are many indications that it is just in this process of change of energy from one form to another that special degrees of activity are to be observed. Such, for example, are the electrical phenomena seen in the oxidation of phosphorus or benzaldehyde, and it appears that, in the photo-chemical system of the green plant, radiant energy is caught on the way, as it were, to its degradation to heat, and utilised for chemical work. In a somewhat similar way, it might be said that money in the process of transfer is more readily diverted, although perhaps not always to such good purpose as in the chloroplast. Again, just as in commerce money that is unemployed is of no value, so it is in physiology. Life is incessant change or transfer of energy, and a system in statical equilibrium is dead.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS BY MRS. HENRY SIDGWICK, PRESIDENT OF THE SECTION.

WHEN I look at the names of many of my predecessors in this presidential chair, when I read their addresses, or when I consider what the work of the Section ought to be, I feel that an apology is needed for my being here at all.

Let me say at once, however, that it is not because of my being a woman that I feel this. It is true that I am the first woman who has had the honour of presiding over Section L. But it is obviously very fitting that a woman should sometimes do so; and this not only because women are as much concerned with the results of educational science as men are—that might be said about all departments of science; nor only because the material on which education works—the human material to be educated—is approximately evenly divided between the sexes. A more important consideration is that women have the largest share in the work of education. This is clear if we take education in its widest and fullest sense, and include in it what is done in the home as well as in the school, beginning as it must with the earliest infancy. But it is also true if we limit the meaning of the word education—in the way that is constantly done, and is I think usually done in the discussions that take place in this Section—to that part of it with which the professional educator, the school or college teacher, is concerned. For the fact that the school teaching, not only of girls, but of the younger children of both sexes, is mainly in the hands of women, results of necessity in there being a larger number of professional teachers among women than among men.

May it not be added that in some departments of education women have appeared to take their profession more seriously than men so far as this can be measured by the trouble taken in training for it? For I think I am right in saying that among persons proposing to teach in secondary schools more women in proportion than men have hitherto availed themselves of opportunities for professional training.

From another point of view, too, the education of women and girls has an interest which, though not different in kind, is greater in degree than that of the other sex. I mean in the rapidity of its growth and development since the middle of the last century. The development of school and university education and of technical education has, of course, been very great for both sexes. Much attention has been devoted to improving its quality, and perhaps even more to increasing its quantity, by making it more accessible to all classes of people. But in the case of girls and women the progress has been greater and more remarkable than in that of boys, for it started from a lower level, and notwithstanding this it would, I think, be difficult to point out in what respects the educational opportunities of women are now inferior to those of men. I say this, of course, in a general sense, and without prejudice as to controversial questions of detail such as the merits of the methods and curricula deliberately adopted for different schools.

The Report of the Schools Inquiry Commission published in 1868, in what it says about girls' education at that time, gives us a standard of comparison and a means of estimating the progress made. It has often been quoted, but may bear quoting again. The Commissioners say:[1]

"The general deficiency in girls' education is stated with the utmost confidence, and with entire agreement, with whatever difference of words, by many witnesses of authority. Want of thoroughness and foundation; want of system; slovenliness and showy superficiality; inattention to rudiments; undue time given to accomplishments, and those not taught intelligently or in any scientific manner; want of organisation—these may sufficiently indicate the character of the complaints we have received, in their most general aspect. It is needless to observe that the same complaints apply to a great extent to boys' education. But on the whole the evidence is clear that, not as they might be, but as they are, the girls' schools are inferior in this view to the boys' schools."

This was what could be said of schools in 1868, and is certainly in striking contrast to what could be said now. And if we turn from the schools to higher education we find this was practically non-existent for women at that time. Its absence was indeed one

[1] Report of the Schools Inquiry Commission, p. 548.

cause of the badness of the schools. The schools were bad because the teachers were inadequately educated. "The two capital defects of the teachers of girls," as one of the Assistant Commissioners (Mr. Bryce, now Lord Bryce) reported, "are these: they have not themselves been taught and they do not know how to teach." These defects were, of course, partly due to the badness of the schools, and the want of any standard enabling the general public and the teachers themselves to judge of their badness. So far it was a vicious circle. The teachers were badly taught in bad schools and handed on the bad results to the schools they later taught in. But the defects were partly due to the absence of opportunity for them to carry their own education beyond that of their elder pupils—to obtain that higher education which men obtained at the universities. This was pointed out by the Commissioners, and their report acted as a great help and encouragement to those who had already realised the need of higher education for women, and gave an important stimulus to the foundation of colleges for women, first at Cambridge and then at Oxford.

The Commissioners' report also greatly encouraged the movement already in progress for the improvement of girls' schools—the movement in which Miss Buss, of the North London Collegiate School, and Miss Beale, of the Cheltenham Ladies' College, were among the pioneers, and in which the opening of local examinations to girls in 1865 by Cambridge was an important step. The cautious and anxious way in which the Commissioners refer to the possible effects on girls of more exacting school work and of examinations is amusing to read now. But the report of the Commission helped in the progress of girls' education in still another way, for it was instrumental in securing the recovery for the secondary education of girls of endowments which had been allowed to lapse into the service of primary education or to be absorbed by boys; and the division between girls and boys of some endowments not specifically assigned to either sex by the founders. Twenty years ago—in 1895—the Charity Commissioners in their annual report gave striking testimony to what has been done both in this way and by new endowments:—

"There is reason to think," they said, "that the latter half of the nineteenth century will stand second in respect of the greatness and variety of the charities created within its duration to no other half-century since the Reformation. And, as to one particular branch of educational endowment, namely, that for the advancement of secondary and superior education of girls and women, it may be anticipated that future generations will look back to the period immediately following upon the Schools Inquiry Commission and the consequent passing of the Endowed Schools Acts, as marking an epoch in the creation and application of endowments for that branch of education similar to that which is marked, for the education of boys and men, by the Reformation."

And the flow of endowments for this branch of education has not ceased since the report just quoted from was written. As examples of it I may remind you of the St. Paul's Girls' School, the extension and rebuilding of Bedford College, University of London, and the large sums given for the domestic department of King's College for Women.

Though, however, as the Charity Commissioners say, a great impulse was given to girls' education by the report of the Schools Inquiry Commission and the legislation as regards endowments that followed, I think that, even without these, great progress would have been made, though probably less rapidly. The desire for it was already there. Women who had themselves suffered from the previous deficiency were working for improvement, and sympathetic men friends were helping. It was becoming more and more obvious not only that women teachers must have adequate opportunities of learning, but that the home no longer in itself afforded sufficient scope for the energies of the daughters, especially unmarried daughters, of the professional classes, and that they must be trained for other useful work. The supply of suitable education followed the demand, as generally happens when the demand is strong and clear. The very mention by the Charity Commissioners in the passage I have quoted of the *creation* as well as of the *application* of endowments for the purposes of female education is evidence of the active public interest in the matter. The spirit which has led during the last half-century to the liberal endowment of education for girls and women from private sources has also led the State, and public bodies generally, to consider girls equally with boys in all public administration of education or of educational funds. The same spirit has led the newer universities without exception to admit women to their benefits on equal terms with men. And at the same time the creation of some professions and skilled industries—*e.g.* sick nursing—by women, and the opening to them of others, together with the general movement in favour of professional training for professional work, have led to the great development of opportunities of technical or vocational training for women as well as for men.

This immense—almost revolutionary—change, as regards educational opportunities for women, which has occurred within the recollection of people of my age, and which must be attributed largely to the efforts of women themselves, is, I think, very striking; and it certainly, as I said, fully justifies the selection of a woman to preside over the Educational Section of the British Association. The apology I feel to be needed is for the particular woman selected. For it is the science of education, or at any rate the science and art of education, that this Section presumably exists to advance, and I am no educator, no teacher; I have made no psychological study of young people from an educational point of view, nor of the different methods of teaching suited to different ages, no statistical investigation of the influence or particular curricula in training the mind or furnishing it with useful information. I have, in short, neither made contributions to the science of education nor practised the art. Any work I have done has been on the administrative side, and I can speak only as a member of the general public—not as an expert. And what is there new, in a subject so much discussed, for a member of the general public to say? An illuminating address is, I fear, in the circumstances impossible.

Not that I regard the view of the general public as unimportant. Indeed, I am not sure that a good case could not be made out for having a mere member of the general public as such as president from time to time. The general public must, as all will admit, decide what is to be spent on education, or, more strictly, on schools and colleges and professional educators, out of both public and private income—it is for them to decide on its relation to other social and family needs. But the concern of the public with education is not merely financial and administrative. It is more intimate than that. For education is not a subject like physics or chemistry on which only an expert has a right to an independent view. There are, no doubt, aspects of it of which only the expert can properly judge, there are experiments in it which only the expert can advantageously try, and there are, of course, departments of it in which the opinion of the expert is indispensable. But without depreciating either the science or art of education, it is clear that

when we take education in its widest sense it concerns everybody, and almost everybody is bound to have views about it. Each generation as a whole is responsible for handing on to the next the control over matter and mind, and the power of co-operation, which it has itself inherited from its forbears and added to, and which it must put its successors in a position to add to further. It is on this that the progress of the human race depends; without it each generation would have to start afresh from the beginning, and we should still be in the position of primitive man.

But the larger and more important part of education in this wide sense is done first in the nursery, and then, as the child gets beyond babyhood, by means of its own observation and imitation of its elders; while much is done by experience gained in mixing with others of its own age, and much by the exercise of responsibility. The education thus obtained, combined with precepts and with tales handed down orally, sufficed for our ancestors until the increasing complexity of life made it important for the rising generation to acquire skill and knowledge which mere imitation and experience could not give. When this happened division of labour took place in this as in other departments of life, and led to the introduction of the professional educator—that is, the educational expert who has the art of imparting the needed knowledge and skill, or at least of shortening the process of acquiring them. We may observe that his services are now required by all, and not, as was once the case, only by those preparing for the learned professions. This work of the professional educator is what our Section of the British Association is mainly concerned with, and the methods to be employed are best judged by the professional educators themselves. But the co-ordination of their work with the whole process of education, its place in the production of good citizens, must, as I have said, be judged, not by the professional educators alone, but by the whole body of the nation. The general public must not only be regarded as capable of exercising judgment on educational matters, but should be encouraged to feel that it is its duty to do so.

If we judge by the amount of talk which goes on about education, it would perhaps seem that the public is fully aware of its responsibilities. And yet I think there are indications that in some respects it fails to grasp them, and is disposed to depend too much on the professional educator; allowing itself to be confused by our habit of using the same word "education" in both the wider sense, of which we have been speaking, and also in the narrower sense of book-learning. The sense of proportion seems to me to be sometimes seriously lost from this cause.

I was impressed with an example of this exhibited a little while ago in a correspondence in the *Times* about the employment of the older boys in the elementary schools of country districts to do some of the work on the farms in place of farm-hands who have enlisted. One group of the correspondents, looking at the question from the point of view of agriculture, thought the advantage derived by the boy from his last year of school training was of small value to the country compared with the work he could do on the farm. The other group, looking at the question from the point of view of the school, thought it monstrous that what they called the "education" of the boy should be in any way curtailed. I am not at the moment concerned with the controversy itself, nor am I taking the side of either group of disputants. There is, of course, much to be said on both sides, and the decision should probably vary with the locality, and the work, and the farmer, and the boy. But what struck me was that all the disputants seemed to regard education as beginning and ending at school. None appeared to think of it in its wider sense. None referred to the great effect it might have on the boy's future life and character to feel that in a grave national crisis he had "done his bit"—an effect which would perhaps be all the greater if he felt he was sacrificing something to make up for which special effort might be needed later. I have seen the view of the gain to boys and girls from helping in the emergency put forward since, but not in the particular newspaper controversy in question, nor, I think, in connection with the loss of a year of schooling.

And there was another aspect of the question which did not seem to excite attention. I mean the possibly bad educational effect, in the wide sense, of preventing the boy from doing the work. To keep him at school, if he was conscious that his services were needed elsewhere, could not but tend to concentrate his attention on himself and the importance of his own schooling, and could not but tend to produce to some extent the deplorable temper of mind which leads some young people, a little older than the schoolboys over whom the controversy raged, to regard self-development as the aim and object of existence. This is certainly not the attitude of a good citizen—and to produce good citizens should, as we probably all agree, be the principal aim of education.

The particular difficulty to which I have referred seems inseparable from compulsory education, and probably cannot be altogether got over. The thoughtful girl of twelve, not absorbed in herself, must sometimes wonder whether her school-work is really as valuable as the help she could give her mother in some special difficulty or strain, except on the assumption that her own development ranks above all other objects.

Of course, the higher the relative value we put on scholastic education the less important will the loss of other educational influences appear to us. And perhaps at this point I had better frankly confess—what is, I fear, another defect in my qualifications as president of the Educational Section—namely, that I am not an enthusiast about education in the same sense that most of my hearers probably are. I read the other day in a review of the life of an American educationist that—

"He was penetrated with two characteristics which are the saving clause of the American and every other democracy, a reverence for learning and a flaming belief in education as the condition of success in any scheme of popular self-government."

In the reverence for learning I am with him, but I could not describe my belief in education—education, that is, in the sense here meant, namely, school and college education—as "flaming." I cannot, for instance, believe, as some seem to do, that by keeping children a year longer at school we should regenerate mankind, or at least secure as a matter of course great improvement. Why, you may ask, if I am not an enthusiastic believer in education, have I spent so much of my life—my time, my energy, my means —in helping to provide opportunities of university education for women? The answer is that I do believe very much in giving to as many people as possible educational opportunities—meaning by that in the first place the means of preparing for their work in life. Those who are going to teach, for instance, must obviously learn first, and, as I have just reminded you, women's opportunity of doing this was lamentably deficient half a century ago.

But secondly—and this is not at all less important—I mean by educational opportunity the means of satisfying intellectual curiosity, every spark of which should be fostered. For it is to intellectual curiosity that progress in knowledge, including physical science,

is mainly due. And intellectual curiosity is an important adjunct to the mental processes involved in understanding the world we live in, a valuable aid in the formation of a good judgment, and a great assistance in practical life. Intellectual curiosity and æsthetic sensibility are, moreover, the mainsprings of culture—that is, of some of the highest pleasures we can enjoy.

You will doubtless agree with this, and will agree, further, that without intellectual curiosity no amount of accumulated information can be properly assimilated, or will produce either culture or knowledge of permanent value. In its absence the pupil may pass through school and college with little advantage apart from discipline, beyond the acquisition of elementary skill in reading, writing, and arithmetic, and if he has a good memory a barren knowledge of some facts. You will probably add that it is one of the most important functions of the teacher to endeavour to produce this intellectual curiosity when absent or in abeyance, and that the zeal of the professional educator in this direction is a strong reason for enthusiastic belief in school education. It would be, I grant, if we could hope that the teacher's success would always be equal to his zeal; but notoriously this is far from being the case, and the failure is by no means always due to want of intelligence in the pupil any more than it is due to want of capacity in the teacher. In many cases, in all classes of society, the spark of intellectual curiosity—the response in the pupil's mind to educational stimulus—cannot be fanned into flame through book-learning alone, and yet may be there all the time ready to burst forth when it comes into contact with the needs of actual life and work. It may even be there, and fail to respond to imposed lessons, while it would blaze up if the pupil could by any means be induced to desire to learn before he is taught. It is partly because it is so important, if and when the desire to learn comes, that the boy or girl, man or woman, should be armed with the instruments which may give them independent means of acquiring the knowledge they desire, so far as this can be acquired through books, that we compel parents to send their children to school. No doubt, however, an even more important reason is our now almost universal use of reading and writing as a means of communicating with each other. The more widespread these arts are, the harder it is for anyone who has not acquired them to keep abreast of his fellows. But even now it would, of course, not be impossible, and the use of such phrases as compulsory education, in which education merely means the reverse of illiteracy, tends, I think, in itself to obscure the apprehension of what education really is, and to reduce the general sense of responsibility for it, and particularly that of parents.

Many years ago, before the days of compulsory education, or at least before it had time to produce any effect, I knew a man in the south of England who had had no school education, or practically none. I believe he could read a little with effort, but he could neither write nor keep accounts, so I was told. His wife did these things for him when they were necessary. He was, however, a good farmer, farmed a considerable amount of land, and acted as manager or agent under the landlord for a large estate. He knew his business thoroughly, had the power of managing men, and was much respected. It is impossible not to regard such a man as a more valuable member of the community, and a better-educated man in some respects, than many of those who climb the educational ladder to become clerks in an office. But, of course, such a man must have regretted that he had not had opportunities of schooling in his early youth—that he had not acquired the art of writing while he still had leisure. The want of the three R's must have been a serious handicap, only overcome by unusual ability. And, in fact, no one now doubts that it is almost as important to acquire these elementary arts as to learn to speak or walk. It is with the question of carrying school education further that doubt arises whether it is really the best education for everybody, and whether we ought to regard the person whose scholastic education has been longest, or who has succeeded best in examinations, as therefore necessarily the best educated.

I do not mean in saying this to set the practical man above the man of learning. Of course we want both, and we should like our schools to help to develop both. The value to the world of good scientific and literary work is enormous. And so far as science is concerned the British Association exists to bring home to the general public its value and interest, and consequently the importance of men who can advance it. Nor do I mean in what I have said to suggest any divorce between practice and learning. The business of most of us is practical, but what is to be desired is that everyone capable of it should combine practical ability—whether in manual work, or in organisation or administration, or in any other line—with a desire to learn; and that not only in relation to his work in life, but in a wider sphere. And, of course, we must wish that the means to satisfy this desire should be within everyone's reach. My point, therefore, is not that learning is not valuable, but that it is of little value unless it meets a desire in the learner's mind. And here the parents come in. The required attitude of mind is much more likely to be inspired by parents who possess it, than it is by the school. Or let us say that those children are most likely to grow up with it whose parents combine with the school to stimulate it. Unfortunately the result of compulsory primary education has not been to promote any sense of responsibility in parents as regards this; at least that is my belief. And I may, I think, appeal to Scottish experience in support of it.

The institution of parish schools is, as is well known, older in Scotland than in England. They date there from the Reformation, and were part of the ecclesiastical organisation initiated by John Knox. In the scheme drawn up by him and his colleagues education had a great place. The parish schools, in which Biblical instruction was foremost, were put in charge of the Church and long needed its efforts for their maintenance. Starting in this way the zeal for school education had become traditional. All respectable parents aimed at giving their children the best education they could. There was a strongly rooted sense of duty in the matter, and this from a double motive. They sent their children to school not only to help them to get on in the world, but because of the traditional association of knowledge and religion. Observe the educational value of this second motive. I am not looking at it from the religious point of view—that is not my business to-day. But as an instrument of culture the value of a desire for learning, based on something other than its relation to worldly success, is obviously great. It may be that the school education actually prevailing in Scotland is better now than that of fifty years ago, that the examination of the school inspector is more searching, if less stimulating, than was that of the Presbytery, that the average or backward child is less sacrificed to the clever one than used to be the case, and that general intelligence is more developed. But the parents, who felt their children's schooling to be their private concern, valued it more, took more personal interest in it, and felt more personal responsibility for their children's progress than parents can do now. And it is a serious question whether the

loss of this close link with home life has not had a bad educational effect, taking education in its wider sense, which is not compensated for by possible improvement in the schools.

I must admit that in saying this I have in mind only a limited area. I have made no wider investigation. The population I am thinking of is an entirely rural one in a purely agricultural district in the south of Scotland, with which I was intimately acquainted as a young woman, and which I re-visit from time to time. In such a district compulsion to send the children to school was unnecessary. It probably was required in the large towns and the more industrial parts of the country. I do not complain of the introduction of compulsion, but it did strike me at the time of its introduction that it was of very doubtful advantage in my own part of the country, and this impression has not diminished since.

To see if it was shared by others I wrote to a friend, more familiar with the district than I am now, to ask whether he did not think that parental interest in the children's school education had decreased, and also whether he thought that, as judged, for instance, by the books they borrowed from the parish library, the grown-up population was less inclined to serious reading than they used to be. I received from him a very interesting reply. He agreed with what I have just said as regards the first question, and after speaking of the warm and genuine wish in old times to give the children a good education, added:—

"The parents might, indeed, let their older children be absent for short times from school for light farm work or the like. But this was more than made up for by the zeal with which they were sent to winter evening classes, which could be gathered then far more easily than now. It is an unfortunate effect of legislation that it has largely deprived us of the great asset we had in the keenness of parental interest. It came about in this way. Government made it compulsory that no child should be employed in wage-earning who had not passed the fifth standard. Almost instantly the ideal of our people was lowered. A child was "educated" who had passed the fifth standard! And when by and by Government made it compulsory that a child should be at school till fourteen years of age, the parents in many cases felt this hard upon them, and our School Board every year has applications for permission to children to work before they are fourteen on various pretexts. I do not say that our people are not interested in their children's education. They still inherit that interest. But *compulsion*, and the fact of the responsibility being taken by Government, has greatly changed their attitude."

With regard to my second question—"Whether there is in country parishes as much reading of serious books, books of weight, history, travels, etc."—he says he "must answer *No.*" He thinks that the young people are perhaps more intelligent than they used to be, "but the reading is in enormous proportion novels and very light literature." He goes on to tell me of an old man who died two years ago "of the finest old Scottish type—devout, independent, interested in religious reading, in lives of men like Livingstone, in travels (he was reading Nansen in his ninetieth year and most interested in his nearing the Pole). But the list of books in his steady reading from the library here was of quite different character from that opposite other names in our catalogue of the same rank." He says also that forty or fifty years ago good audiences could be got for lectures—historical, travel, etc., but that now a good audience can only be got for concerts, entertainments, or at most lectures with lantern pictures. All this seems, so far as it goes, to show a diminution in culture, in capacity for the higher intellectual pleasures, in fruitful curiosity. My correspondent is not prepared, however, to say that this change is due to changes in school education. It comes, he thinks, "of the different spirit in young people, less under authority, indulging more in pleasures, not pressing hard or thinking they need this in order to get on." He thinks, in short, that the young men now are more self-indulgent and less energetic than they were, and he looks to the nobler spirit which the war has called out to carry us into better ideals of life. He may be right in thinking that causes independent of school education have produced the result. But we must admit that if it is true that, concurrently with a school education improved in some important ways, there has been a diminution in intellectual interests—in culture, in short—the school education has at any rate failed in one of the objects aimed at.

Well, you must take these views about a particular country district for what they are worth. Facts observed among a comparatively small number of people may not represent the average. Moreover, my correspondent and I are both old—we could not remember, or think we remembered, the state of things fifty years ago if we were not—and you may, if you think proper, discount what we have to say, on the almost proverbial ground that old people put the Golden Age behind them. I am not, however, myself conscious of any such tendency. I believe very much in progress, and look forward to a gradually improving world, and I believe we are on the whole improving in educational ideals and educational methods as in other things. But it behoves us to watch what we do, and not to acquiesce, if we can possibly help it, in loss on one side without being very sure that it is more than compensated for by gain on the other. The loss of the parents' real co-operation where it has existed, and the failure to gain it where it has previously been absent, is serious. It is serious even if it is limited to the intellectual side of education and does not extend to the formation of character, as I fear it sometimes does. With the greatest zeal the schoolmaster cannot replace the parents, nor even the parents' influence in producing the right attitude of mind in the pupil. And it is at the very least doubtful whether the better teaching which improved methods secure to the pupil can make up for any loss of spontaneous desire to put his own mind into the effort of learning for learning's sake.

And so I come back to the point that the general public must be encouraged to take its share even in the part of education carried on at school and college, and in particular those members of the general public who are parents of pupils. But this conclusion is rather barren, for I have no very definite plan to suggest for carrying it out. The State cannot now, even if it would, abandon the responsibility for the elementary school education of the children, and even if it could it is more than doubtful whether it would be desirable. For though we have now secured that all parents shall themselves have had school education, we still cannot trust them all voluntarily to give that advantage to their children. So the drawback must be put up with that parents cannot feel the same degree of responsibility resting on themselves when the responsibility is undertaken by the State.

It is to be hoped, however, that we shall be very careful how far we entrust to the State the regulation of education higher than the primary. Bureaucratic regulation may be well adapted to produce German *Kultur*, but it is not the way to secure the attitude of mind which leads to freedom, independence of thought, and culture in the best sense. And it is very apt to lead to want of independence in the teacher.

Probably our best hope for progress in the right direction lies in movements like the Workers' Educa-

tional Association, where we have voluntary effort put forward to satisfy spontaneous desire to learn. As this movement extends we may hope more and more to get a generation of parents who, having themselves experienced intellectual curiosity and the joy of satisfying it, who, having themselves felt the gain of a wider outlook on men and things, may by their example inspire their children with a similar disinterested desire for learning and culture.

NOTES.

THE members of the Siberian Expedition sent out from this country sixteen months ago, at the joint expense of the Oxford University School of Anthropology and the Philadelphia University Museum, reached London last week. The leader, Miss M. A. Czaplicka, possessed exceptional qualifications for the work entrusted to her, being a native of Russian Poland, and a distinguished student of the Warsaw University and of Somerville College, Oxford. The expedition consisted of Miss Curtis, the artist, Miss Haviland, ornithologist, and Mr. Hull, of Philadelphia University, ethnologist. They proceeded from Warsaw to Krasniack, in Siberia, and thence to the mouth of the Yenisei. The first tribe examined was that of the Samoyeds, and then the winter was spent among the Tungus of the Tundra, a very primitive race, little influenced by Russian culture. The spring was devoted to the Tartars, who are much more civilised than either the Samoyeds or the Tungus. Much information of scientific interest has been acquired, and a large collection of costumes, weapons, implements, and ornaments made of copper and iron has been made. These will, it is hoped, be exhibited in Europe and America after the close of the war.

THE Admiralty Air Department has been reorganised and for the future will be under the direction of a flag officer, with the title of Director of Air Services. Rear-Admiral C. L. Vaughan-Lee has been selected for this appointment. He held the post of assistant to the Director of Naval Ordnance from February, 1899, to July, 1900, and of Assistant Director of Naval Intelligence from January to December, 1905. The Director of the Air Department, Commodore M. F. Sueter, C.B., has been promoted to the rank of Commodore 1st Class, and will be in charge of the *matériel* side of naval aeronautical work, with the new title of Superintendent of Aircraft Construction. Commodore Sueter was appointed Inspecting Captain of Airships in September, 1910, and in 1912 he was selected for the post of Director of the Air Department.

AN exhibition of the various forms of apparatus found most useful in the treatment of fractures met with in the war will be held in the premises of the Royal Society of Medicine, 1 Wimpole Street, W., from October 7 to 11. During the exhibition Sir Almroth Wright will demonstrate his recent researches in the drainage of wounds.

WE learn from the *Kew Bulletin* that Mr. W. G. Craib, assistant for India in the Kew Herbarium, has been appointed assistant to the professor of botany in the University of Edinburgh, with the status of University lecturer on forest botany and Indian forest trees, Royal Botanic Garden, Edinburgh. Mr. J. Hutchinson succeeds Mr. Craib at the Royal Gardens, Kew.

THE death is reported, in his eighty-second year, of Dr. Carlos J. Finlay, who was associated with the discovery of the part played by the mosquito in the transmission of yellow fever and other diseases. He was a native of Cuba, and received his general education at the Lycée at Rouen, and his professional education at the Jefferson Medical College, Philadelphia. He then returned to Cuba and became one of the leading physicians in the island.

THE death is announced in *Engineering* for September 10 of Mr. G. W. Manuel, who for twenty-one years was superintending engineer to the Peninsular and Oriental Steam Navigation Company. Perhaps his strongest characteristic was his determination that the P. and O. mail liner should reach its port according to scheduled time without the variation of a minute, and no development was made unless he himself was perfectly satisfied that it could be relied on and would conduce to punctuality. Mr. Manuel became a member of the Institution of Naval Architects in 1879, and contributed frequently to debates. His death will be regretted by many sea-going engineers who have come under his influence.

WE regret to see the announcement of the death, on September 14, at eighty-five years of age, of Sir John Knox Laughton, distinguished particularly by his studies in naval history. Sir John Laughton entered the Navy in 1853 as a naval instructor, and was mathematical and naval instructor at the Royal Naval College, Portsmouth, from 1866 to 1873. He was then transferred in the same capacity to the Royal Naval College at Greenwich, becoming also lecturer on meteorology. In 1885 he retired from active service on being appointed professor of modern history at King's College, London, and from that date until his death he devoted himself almost entirely to studies of naval history. In addition to valuable works upon this subject, he was the author of volumes on "Physical Geography in its Relation to the Prevailing Winds and Currents," and "A Treatise on Nautical Surveying." From 1882 to 1884 he was president of the Royal Meteorological Society.

JULIUS PAYER, the discoverer of Franz-Josef Land, whose death on August 31 was announced in our last number, was born in Bohemia in 1841. He served with distinction in the war with Italy in 1866, before he joined the second German expedition to east Greenland in the *Germania*, under Koldewey, in 1869. There he acquired much experience in polar work, in the exploration of King William's Land and the extraordinary Franz-Josef Fjord. In 1871, through the liberality of Graf Wilczek, Payer and Weyprecht undertook an expedition in the *Isbjörn* to Spitsbergen and the Barents Sea as a preliminary to an Arctic expedition on a large scale. This expedition, the first to explore the north of the Barents Sea, was fruitful of discoveries there and in Spitsbergen and Hope

Island. The Austro-Hungarian Arctic Expedition sailed in 1872 in the *Tegetthof*. Weyprecht was again associated with Payer in the command. Their aim was to push north-east of Novaya Zemlya and return to Europe *viâ* the Behring Strait. From the first they met with misfortune. The *Tegetthof* was beset in the ice in 76° 22′ N., 63° E., and drifted with the pack throughout the winter in hourly danger of destruction. Twelve months later high land was sighted to the north-west and named Franz-Josef Land. A landing was made on one of the islands. A second winter was passed on the ice-bound ship, and in the summer of 1874 Payer conducted several sledge expeditions to explore the new land. Passing up Austria channel, he reached Cape Fligely in Rudolf Land in 81° 51′ N. North-eastward he saw further land, which he named King Oscar and Petermann Lands. In May the *Tegetthof* was abandoned, and after terrible hardships to get clear of the ice the expedition reached Novaya Zemlya in open boats in August, 1874. An English version of Payer's narrative, "New Lands within the Arctic Circle," appeared in 1876. In 1875 Payer was awarded the patrons' medal of the Royal Geographical Society.

IN the course of excavations on the site of the great city of Pataliputra, the modern Patna in Behar, a discovery of much interest has been made. A vast pillared hall of the Maurya period, the third century B.C., has been unearthed. It contained eight rows of monolithic columns, fifteen feet apart, supporting a wooden superstructure which has been destroyed by fire. Some remarkable constructions of *sâl* wood beams have also been found, the object of which is uncertain; they may have been platforms for mooring boats, or supports for another portion of the building. The type of architecture at once recalls the great hall at Persepolis, and we have thus a further indication of the influence of Persian art on India during this period.

THE great Buddhist Emperor, Asoka, was in the habit of inscribing his edicts on monolithic pillars or on rocks throughout his wide dominions. The Buddhist pilgrim, Hiuen Tsang, mentions specifically sixteen such pillars. Up to the present ten have been discovered, but only two of these can be identified with those mentioned by the traveller. The rock inscriptions, of which twelve have already been found, though not possessing the artistic interest of the pillars, are in some respects the most valuable monuments of his reign. The recent discovery of another rock inscription by some gold prospectors at a place not far from Raichur, in the Dominions of the Nizam of Hyderabad, is now announced. The Government epigraphist, Rao Sahib H. Krishna Sastri, is satisfied that it is a rock inscription. As the texts of these documents vary, the publication of the inscription will be awaited with interest.

SOME admirable photographs of the adult and nestling of the Asiatic golden plover, and a most excellent account of the breeding habits of this bird, by Miss Maud Haviland, appear in the September issue of *British Birds*. The most important of her observations are such as concern the behaviour of apparently non-breeding birds of this species. On two points, however, she might well have been a little more explicit. The reader is left in doubt, for example, as to whether the newly-hatched nestlings accompany their parents, from the high to lower grounds, to participate in the formation of the flocks of which she speaks, and it would have been helpful to have had a more precise description of the plumage of the fledgling. Following Miss Haviland's paper comes a brief account, by Mr. C. W. Colthrup, of the idiosyncrasies of the nidification instinct in the redshank. Within the confines of the same marsh in Hampshire he found eggs in comparatively elaborate nests and screened from view by overarching stems of grass, while in other cases the eggs were laid in an apology for a nest, and without any attempt at concealment.

IN the *Philippine Journal of Science*, vol. x., No. 1, Mr. R. P. Cowles contributes some extremely interesting notes on the habits of some tropical Crustacea. He deals more especially with the remarkable feeding habits of *Atya molluccensis*, and of several species of Caridina, and the peculiar structural modification of the chelæ associated therewith. In both genera the chelæ or "nippers" are armed with hairs, which, in Atya, can be opened to form funnel-shaped strainers for the capture of minute organisms, and closed to form a pencil-like brush, imprisoning the food thus captured, which is then conveyed to the mouth. While feeding, Atya, which is an inhabitant of running streams, remains perfectly still, with its strainers directed upstream. Caridina, with similarly armed chelæ, crawls about on the bottom of the stream, and uses the hairs, not as strainers, but as brushes, to sweep the bottom of the stream for minute particles of animal and vegetable matter. Mr. Cowles supplements these notes with valuable observations on the habits of *Myctris longicarpus*, which appears in countless numbers on sand-banks exposed at low tide. When the tide rises they immediately disappear beneath the sand. During their migrations they are continually smearing the sand over the mouth with the chelæ, apparently for the sake of the nourishment to be derived from the particles of animal matter it contains. These creatures are extremely difficult to approach, for on the slightest alarm they at once proceed to dig themselves into the sand, vanishing in about three seconds.

THE recently issued part of Contributions from the United States National Herbarium, vol. xvii., part 6, is entirely occupied by an enumeration of the tropical North American species of Panicum by A. S. Hitchcock and Agnes Chase. One hundred and sixteen species and three subspecies are included, nine of which are new. The total number of species of Panicum in North America is now 216. Each species is accompanied by an outline map graphically representing its geographical distribution within the tropics of North America. There is also a key to the species and groups, and a complete list of the localities for each species is given.

A CATALOGUE of the soft-water algæ collected in the Caucasus in the region of Czernomorsk is published

by M. A. I. Lobik in the Bulletin of the Imperial Botanic Garden of Peter the Great, vol. xv., No. 1, 1915. Sixty-five species are enumerated; they include one Floridean alga, *Batrachospermum moniliforme*, one brown alga, *Hydrurus foetidus*, twenty-five Chlorophyceæ, twenty-four diatoms, and fourteen members of the Cyanophyceæ. Among the Chlorophyceæ a new form of Spirogyra and of Cosmarium are described, and also a new genus, Leptobasis, among the Cyanophyceæ. This new alga, *L. caucasica*, forms the subject of a separate memoir by M. A. A. Elenkin, who, with M. V. P. Savicz, made the whole collection. Elenkin, in determining the new genus, revises the old genus Michrochæte, and considers that the genera Michrochæte, Coleospermum, and Leptobasis should be classed in different sections of the Hormogoneæ. The paper is illustrated with text figures.

IN the *Philippine Journal of Science* for May (vol. x., No. 3), Mr. E. D. Merrills contributes four papers dealing with Philippine botany, and describes a number of new species of the genera Schefflera and Eugenia. In the opening paper on the present status of botanical exploration in the Philippines, which is illustrated by a map of the group, Mr. Merrill gives interesting particulars showing the amount of work which has been accomplished during the past thirteen years, and the parts of the archipelago which have been thoroughly explored. Compared with Java, Singapore, and Penang, the flora is not well known, and though much work has been done it has been confined to a few definite areas in Luzon and Mindanao. The islands are so densely forested that even in those regions visited by botanists on short excursions only a tithe of the plants has probably been collected, and a large number of endemic forms doubtless await discovery. Some fifteen years ago 2500 species of flowering plants were recorded from the islands; now the number is estimated at rather more than 7000, and it seems probable that 10,000 species is not an extravagant estimate for the phanerogamic flora of the Philippines. Some 40 per cent. of the whole Malay Archipelago flora will probably be found to be endemic in the islands.

TARE-LIKE rogues appear from time to time among culinary peas, and are characterised by the possession of stipules and leaves narrower and more pointed than those of normal plants. The pods also are distinct, since they are always curved and narrow, even though the races in which the rogues have arisen bear straight pods, and the seeds are less sweet than those of the types. The seed-raiser has attempted to eliminate the rogues by destroying them as they appear, but all to no purpose; the rogue still reappears, and with the object of understanding its origin and finding a means of control, Mr. Bateson and Miss Pellew have conducted a series of investigations at Merton, and have published their results in the *Journal of Genetics* (vol. v., No. 1) for July. Though the research has been extended and a large series of plants examined, the origin of the rogue is still a mystery, nor has a method been devised as yet for the elimination of these tare-like plants. Rogues may depart widely or only slightly from the type; in the latter case rogue characters may only appear in the youngest parts, but as such plants can produce complete rogues among their offspring they should be weeded out. Rogues in breeding beget only rogues, and even in a strain of quite normal plants rogues occasionally appear. One remarkable result of the inquiry is that normal plants crossed with rogues always give rogues, and this was found to be true in fifty out of fifty-two crosses, and to persist through three generations.

THE methods of bacterial analysis of air have recently been investigated by Mr. G. L. Ruehle in the course of an inquiry into the contamination of the air of cowsheds and its effects on the milk supply. In vol. iv., No. 2, of the *Journal of Agricultural Research*, a large number of comparative analyses is described in detail. Three forms of apparatus were used: (1) the standard sand-filter aeroscope of the American Public Health Association; (2) a modification of the standard designed by the author to permit sterilisation by dry heat; and (3) the Rettger liquid-filter aeroscope. The efficiency of the aeroscopes was tested by running two of each type in tandem so that the air passes through one filter and then through the other. The percentage of the total number of bacteria caught by the first filter determines the efficiency. The standard aeroscope was found to have a very variable efficiency, averaging 90 per cent., but the modified standard retained nearly 100 per cent. of the bacteria. The Rettger apparatus also gave excellent results, but required greater care in manipulation, as difficulties occur with foaming of the liquid during filtration and the tenacity with which the bacteria cling to the inner surface of the moist inlet tube. The method of determining bacterial precipitation from air by exposing Petri dishes is quite untrustworthy, as it only measures the number of bacteria-laden dust particles falling on the plate. The exposure of sterile water in pails gives an average bacterial count ten times higher than that obtained by the plate method.

WE have received vol. xxvi. of the *Anales* of the National Museum of Natural History of Buenos Aires, containing a useful index to the first twenty volumes of this publication (1864–1911), and an interesting illustrated account of the fine new building for the museum which it is hoped will soon be provided by the Argentine Government. Under the energetic direction of Dr. Angel Gallardo, the technical scientific work of the museum has become very varied, and the newly-published volume contains several valuable contributions to systematic zoology and botany. There is also an exhaustive study of the collection of human skulls from Patagonia, with numerous tables of measurements. The most generally interesting research is a new examination of the deposits on the coast of the province of Buenos Aires containing human remains or implements made by man. This has been instigated by the criticisms of Argentine discoveries published by Drs. Hrdlička, Holmes, and Willis in their work on "Early Man in South America" (Smithsonian Institution, 1912). It is maintained that in the neighbourhood of Mar del Plata and Miramar there is no reason to doubt the association of evidence of man with late Tertiary

mammals, and a femur of a small Toxodont is described by Mr. Carlos Ameghino, showing a piece of worked quartzite which must have penetrated the bone during life.

THE Avezzano earthquake of January 13 last originated in a portion of Italy in which strong earthquakes are of infrequent occurrence. One of its latest predecessors, that of February 24, 1904, has been studied by Dr. A. Cavasino (*Boll. Soc. Sis. Ital.*, vol. xviii., 1914, pp. 411–48), and his conclusions are of interest in connection with the recent earthquake. The area of destruction contains only 54 square miles, and its centre lies about seven miles north-west of Avezzano. The two earthquakes were therefore in all probability associated with the same fault. As the disturbed area includes only about 4750 square miles, the focus cannot have been at a great depth. Using Dutton's method, Dr. Cavasino estimates that depth to be about 4½ miles.

A SUMMARY of the weather for the past summer is given in the issue of the Weekly Weather Report of the Meteorological Office. The period comprises the thirteen weeks from May 30 to August 28, and the aggregates of temperature, rainfall, and bright sunshine are given for the several districts of the United Kingdom. The mean temperature was below the average everywhere except in the north of Scotland, where the excess was less than 0·5°; the deficiency amounted to a degree in the south-east and south-west of England, and in the English Channel, whilst in other districts it was generally about 0·5°. The east of England was the only district with the absolute maximum temperature as high as 90°, and in all the western districts the thermometer failed to reach 80°. Rainy days were in fair agreement with the normal, whilst the total rainfall varied considerably in different parts of the United Kingdom. There was a deficiency of rain in the north and west of Scotland, the north of Ireland, the north-west and south-east of England, and in the English Channel; the greatest deficiency was in the west of Scotland, where the rainfall was only 72 per cent. of the average. There was an excess generally in the eastern district, in the south-west of England, and in the south of Ireland; the greatest excess was 123 per cent. of the average in the east of England. Bright sunshine differed very little from the normal, and the only districts with an excess were the north of Scotland and the north-west of England.

THE number of the Proceedings of the Tokyo Mathematico-Physical Society issued in June, 1915, contains a *résumé* in English by Mr. Tokurô Nakano of a magnetic survey of Japan for the epoch January 1, 1913, executed by the Japanese Hydrographic Office under the superintendence of Prof. Tanakadate. There were four survey parties in the field, and the whole of the observations were concluded within fourteen months, so that uncertainties arising from secular change were unusually small. A previous survey had been made for the epoch January 1, 1895, also under the supervision of Prof. Tanakadate, and the same instruments and a good many of the same stations were employed on the two occasions. A still earlier survey was executed in 1887 by Profs. C. G. Knott and Tanakadate. The 1913 survey, however, unlike the earlier ones, was not confined to Japan proper. Of its 331 stations, 78 were in Korea and 16 in Formosa; 38 of them were adjudged disturbed and left out of account in deducing the isogonals, isoclinals, and isodynamics. Formulæ were found for the values of the different magnetic elements, proceeding in powers of the latitude and longitude differences. Tables based thereon give the calculated values of the declination, dip, and horizontal force at the intersections of degrees of latitude and longitude. Similar formulæ were found for the secular change, and even for the rate of change, or "annual acceleration," of the secular change. The secular change conclusions were based on the results from fixed magnetic observatories and from stations common to two or more of the surveys.

THE Transactions of the Royal Society of South Africa, vol. iv., parts 1 and 3, 1915, contains three papers by Prof. J. C. Beattie dealing with terrestrial magnetism in South Africa. The first paper, read July 16, 1913, gives the values of declination, dip, and horizontal force observed by Prof. Beattie himself at about ninety stations in the years 1910 to 1913, and values of the declination observed by Mr. O. C. Macpherson at seven stations in 1909. Some of the ninety stations had been previously observed at by Profs. Beattie and Morrison during their survey of the epoch July 1, 1903. The new parts of the country dealt with included the West Transvaal, British Bechuanaland, and Bushmanland. The second paper, also read on July 16, 1913, gives a table of values of declination, dip, and horizontal force for the epoch July 1, 1908, at 255 South African stations. The observations had been made at various times from 1900 to 1913, the reductions to a common epoch depending on the secular change results obtained from repeat stations. There are three charts representing respectively the isogonals, the isoclinals, and the lines of equal horizontal force for the epoch considered. The third paper, read May 20, 1914, discusses the secular variation of the magnetic elements in South Africa between 1900 and 1913. There are three charts showing respectively the mean annual changes of declination, dip, and horizontal force. Westerly declination is falling throughout the whole of South Africa, the rate of fall being especially large—from 10′ to 13′ annually—along the east coast as far north as Mozambique. The southerly dip is increasing rapidly, but in this case the rate of change is largest—8′ per annum—in the neighbourhood of Cape Town. Horizontal force is diminishing rapidly, the annual fall in Cape Colony varying from 85γ to 100γ per annum. There are few parts of the world where so large secular changes have been observed, thus magnetic observations in South Africa are of exceptional value.

THE London Mathematical Society has issued, with the assistance of its official printer, Mr. T. T. Hodgson, a list of suggestions for notation and printing of mathematical formulæ, accompanied by a sample illustration showing the leads, spaces, and quadrats required in mathematical composition. Most of the suggestions might be summed up briefly in the

general statement that every symbol or sign introduced at a different level to the rest involves extra spacing, although this objection does not apply to the use of the ordinary indices and suffixes, or to the use of two lines to represent fractions in a line consisting entirely of formulæ. The use of a bar over a square root is objectionable, but we would suggest that the proposal always to use Roman or Greek *i* for the root of -1 is scarcely necessary, as the bar can be omitted in this case without ambiguity. The use of fractions in the middle of a line of letterpress produces an unsightly result. While agreeing with the suggestion that the small numerical fractions which are usually cast as single pieces of type can often be used with advantage, it should be noticed that "thirds" are not easy to distinguish from "eighths," and the solidus notation may often be used to overcome this difficulty. The avoidance of letters with bars or dots placed above them, to which much importance is attached, is a change which may often present difficulty, and it is doubtful how far the proposal to substitute dashes in the fluxional notation will be found practical in view of the frequent use of dashes for other purposes. There is, however, no reason why the raised dots should not be placed after instead of over the letters, while inverted commas offer another new opening, hitherto neglected. We should like to see "exp." included in the list of suggestions. But if writers of papers are sometimes to blame, printers have an awkward way of beginning a formula at the end of one line of letterpress and continuing it in the next line, even when the author has not done so. And we think the printers might at least take on themselves the responsibility of removing the bars over square roots. When, however, a paper refers to the rigid dynamics of aeroplane motions, the number of symbols required is so great that violation of every rule becomes inevitable.

IN the second part of vol. iv. of the Science Reports of the University of Sendai, Prof. K. Honda describes a balance which allows the effect of temperature on any chemical change involving loss of material by evaporation or dissociation to be followed readily. The beam of the balance is a silica glass tube from one end of which a small platinum or magnesia vessel to contain the specimen is suspended, within an electrical heating coil enclosed in turn in a Dewar vacuum vessel. The other end of the beam is pulled down by a spiral spring, the pull of which can be adjusted to suit the specimen used. The movement of the beam is observed by means of a mirror attached to it and a telescope and scale, a deflection of a millimetre corresponding to about half a milligram. The temperature of the specimen is observed by means of a thermo junction, and is raised about a degree per minute. Curves showing the loss of water of crystallisation of two sulphates, the dissociation of a carbonate, and the change of chromic oxide with temperature are given.

"RED BOOK" No. 198 of the British Fire Prevention Committee contains the report of a fire test with three window openings filled with wired glass. These were subjected to the committee's standard 60-minute test at temperatures reaching up to 1600° F., followed by the application of water under pressure. The usual test size of glazed panels is about 2 ft. by 2 ft., but one of the panels under test in this case measured about 3 ft. by 2 ft. The classification of temporary protection (Class B) under the committee's standards has been accorded for this glazing to this larger size. Partial protection (Class A) has already been obtained for wired glazing by the same makers (Messrs. Pilkington Brothers, Ltd., St. Helens), both for regulation sizes and for a panel measuring about 4 ft. by 1 ft. In the present tests, in the case of two of the panels, neither fire nor water had passed through the glazing at the conclusion of the test, and the glazing remained in position after the application of water. In the third panel (two lights) fire had not passed through the glazing, but on the application of water the glazing in the lower light was perforated at the top portion, and some water came through. In this case also the glazing was in position after the application of water.

MR. JAMES HORSFALL, late chief draughtsman of the Canadian Pacific Railway, suggests an improvement in the design of locomotive coupling and connecting rods. Such rods are subject to reversal of stresses due to the alternate push and pull, and also in the bending due to the action of centrifugal force. The effects of the latter may be reduced considerably by prolonging the rods beyond the pins and attaching balance weights to the extensions so formed. By suitably adjusting the proportions, the bending moment at the middle of the rod may be made zero, and the maximum bending moment on the rod will be much less than in the same rod unbalanced. Mr. Horsfall says that, as the result of very numerous experiments with rods of various kinds, he is convinced that the best way to avoid danger from the breakage of coupling and connecting rods is to counterbalance them in the manner suggested.

OUR ASTRONOMICAL COLUMN.

COMET 1915*d* (MELLISH).—The discovery of a second comet during the present year by Mr. J. E. Mellish, Madison, Wis., U.S.A., was announced last Thursday in a telegram from Copenhagen. On September 6, at 22h. 9·1m., the comet's position was α 6h. 30·2m., δ 8° 50′ (approx. 8° south of γ Geminorum). No information was supplied regarding the direction or rate of the comet's motion, or of its magnitude.

SATURN.—Dr. Percival Lowell, in a letter to M. Flammarion (*L'Astronomie*, August, 1915), describes observations made at Flagstaff during last spring. Photographs were secured on March 12, when the ring system was practically at maximum apparent breadth. Cassini's division appeared continuous. With the planet thus framed in its rings a new determination of the aplatissement has been possible, giving the value 1/9·18

RADIAL VELOCITY, MAGNITUDE, AND SPECTRAL TYPE.—Mr. C. D. Perrine has published (*Astrophysical Journal*, vol. xli., pp. 396–99) the results of further analysis of the data in Campbell's lists of radial velocities. Dividing the stars into two groups according to magnitude, drawing the line at 3.0m., he finds a decided increase of the mean radial velocity for the fainter group; this also holds for the stars of each

spectral type separately (except only the A stars), and the effect appears to be more marked in the later types. Further, the highest known velocities are found in the vicinity of the Milky Way. It is conjectured that the effect may be due to the operation of a resisting medium on stellar bodies differing in size and density, or the closer proximity of the fainter stars to a "source of general gravitational action." In either case the Milky Way would be deeply concerned.

In another note in the same journal Mr. Perrine analyses the spectral distribution of the stars of large radial velocity, finding the maximum mean values among the faint stars of classes F and G.

VOLCANIC DUST VEILS AND CLIMATIC VARIATIONS.—Fluctuations in the observed intensity of the solar radiation have been interpreted during the past ten years or so as traceable to the screening effects of the enormous quantities of dust poured into the upper atmosphere during notable volcanic eruptions; thus it has been a small step to the wider hypothesis that volcanic dust has been a possibly important factor in the production of past climatic changes. This hypothesis is tested by Mr. Henryk Arctowski in a paper communicated to the New York Academy of Sciences (Ann., Vol. xxvi., pp. 149–174, June, 1915). Previous work on temperature records had led him to the conclusion that a general rise in the temperature of the atmosphere was probably due to an increase in the solar constant itself. From a re-examination of temperature curves, chiefly showing departures from monthly means, paying special attention to the epochs of the Krakatoa (1883) and Katmai (1912) eruptions, as well as the year 1902, which was marked by intense vulcanism in both hemispheres, he now concludes that the short-period variations of temperature have nothing in common with the presence or absence of volcanic dust veils, although minor secondary modifications of the temperature curve may sometimes be traced to this cause. He finds that the sun-spot variation does appear to have an influence on atmospheric temperature, and, moreover, presumes, but does not explain, the existence of a correlation between the temperature changes and frequency of volcanic eruptions.

THE AURORA BOREALIS.—An illustrated account was given in NATURE, August 7, 1913, of the photographic observations made by Prof. Carl Stormer, in collaboration with M. Bernt I. Birkeland, in the spring of 1913. These observers were stationed at Bossekop and Store Korsnes respectively. They secured a great wealth of parallax material which will require a long time for reduction. However, one-sixth having been finished, Prof. Stormer has published a preliminary report ("Terres. Mag. and Atmos. Elec.," vol. xx., No. 1). Some six hundred measures of altitude have been worked out, most of the measured points lying between 90 and 130 km. above the earth's surface; none come out appreciably lower than 90 km., whilst the highest reaches 230 km. From a mere inspection of the diagram the mean height appears to be about 120 km.; thus the lower limit is fairly well marked. The spatial relations of a number of auroral curtains have been worked out in detail. In one case this information has been used in conjunction with magnetograms from the Haldde Observatory, to obtain an idea of the nature of the aurora. The curves show that the magnetic effect due to the passage of the particular auroral feature had components directed N.W. and upwards. On the assumption that the display was caused by electric corpuscles travelling towards the earth, Ampère's rule indicates that the observed deflections would result from the motion of particles carrying a positive charge.

AMERICAN HYDROIDS.[1]

MR. NUTTING may be congratulated on the completion of the third part of his great monograph on American Hydroids. He has a generous conception of America, and includes in his list such species as *Sicularia hemisphaerica* from S. Tierra del Fuego and *S. repens* from Kerguelen. It is therefore almost a monograph of the hydroids of the world, and will be regarded as the most important work of reference on the group that has yet been published. Those who are specially interested in Cœlenterata will probably be gratified to find that Mr. Nutting has taken a conservative attitude as regards species, and that, notwithstanding the many temptations to which he has been exposed in the course of his vast labour in this field, he has added very few new species to those already recognised. It is a much easier method—and a particularly attractive one in the preparation of a standard treatise on systematic zoology—to make new species when difficulties arise than to exercise the skill and patience that is required to place doubtful specimens in their proper specific groups, and we may regard it as a sign of Mr. Nutting's knowledge and thoroughness that the list of species is not a longer one.

The method adopted in dealing with the species is to select a specimen regarded by the author as typical, to give in a footnote the locality from which the specimen came, and then to describe it in detail. There is much to be said for this method in dealing with the systematics of Cœlenterata, because it gives the systematist a fixed point, as it were, around which the variants may be grouped, but it seems to us that to that description of a type some statement should be added of the principal variations observed by the author in the species under consideration in order that future workers in the group may find that some of the difficulties they are sure to meet with in using the monograph as a standard work of reference have been anticipated by a recognised authority.

The author has evidently taken infinite pains to collect from all available sources specimens of American hydroids for study and description, and his reference lists at the head of each species are extraordinarily complete and accurate. Our thanks are due to him for a very valuable work. S. J. H.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE Board of Education informs us that the regulations and syllabuses which governed the examinations in science and technology held in 1915 will continue in force for 1916. In the prefatory note to the volume of regulations and syllabuses for examinations in science and technology, 1915, the Board announced its intention to discontinue those examinations at a date to be afterwards announced. The Board now gives notice that after 1916 it will no longer hold lower general examinations in any subjects of science and technology. The higher general examinations will for the present be continued.

THE prospectus for the forthcoming session of the Belfast Technical Institute has now been published. An interesting departure is the indication by an asterisk prefixed to the name of the members of the permanent staff who are at present serving in the Army or Navy, or who are engaged on war service. The number of asterisks is excellent testimony to the

[1] "American Hydroids." Part III. The Campanularidæ and the Bonneviellidæ. Smithsonian Institution. Special Bulletin. Pp. 126+70 text figures+27 plates. Washington, 1915.

loyalty of the staff. The prospectus follows the general lines of previous years, and is, as usual, profusely illustrated. The Queen's University of Belfast and the Corporation of Belfast have entered into an agreement whereby the Technical Institute is recognised as a college in which students of the University may pursue a course, or part of a course, of study qualifying for a degree or a diploma of the University. The degrees obtainable are those of bachelor, master, and doctor of science. The departments recognised are those of mechanical and electrical engineering, chemical and textile technology, architecture and naval architecture. The day technical college has been established to provide instruction in the science and technology of mechanical and electrical engineering, the textile industries, and pure and applied chemistry, and gives a sound training for youths who aim at filling positions of responsibility in the various industries. Belfast may be congratulated upon the enterprise which has resulted in the establishment of an institution in which its young citizens can equip themselves fully for their parts in the industrial life of the community.

THE new session of the Battersea Polytechnic opens on September 21, and particulars of all the courses and classes are given in its calendar, which is now available. Full day and evening courses in preparation for the University of London intermediate and final degree examinations in science, engineering, and music have been arranged. In the day technical college, courses are arranged in mechanical, civil, electrical, and motor engineering, architecture and building, and chemical engineering. The training department of domestic science offers courses in preparation for the teachers' diploma in domestic subjects. The department of hygiene and physiology provides complete courses in training for women sanitary inspectors and health visitors. Full evening courses are provided in the various departments. In addition to its usual work, the polytechnic has adapted itself to meet the needs occasioned by the war, and the following will give some indication of what is being done:—Special Red Cross courses in first aid, home nursing, cookery, and laundrywork for women are being held. Belgian refugees are admitted to classes free of fee, and many such students have taken the motor-car engineering course, with a view to war service in France or Belgium. The mechanical engineering department is engaged in the manufacture of munitions, and the chemical department on the preparation of chemical substances for the Government. So far as is known at present 384 members of the polytechnic governors, staff, and students have joined the Forces, and at least forty-three of these hold commissions.

THE calendar for the next session, which is the hundred and twentieth, of the Royal Technical College, Glasgow, has reached us. It will be remembered that in 1913 the college was affiliated to the University of Glasgow. Candidates for the degree of B.Sc. in applied science may attend the necessary qualifying courses either in the University or in the college, or in both. A noteworthy testimony to the value of the instruction given at the college is its recognition by various professional bodies and Government departments. Thus, success in the civil engineering courses exempts from the examinations of the Institution of Civil Engineers; the college has been recognised by the Board of Trade as suitable for the training of marine engineers; the Home Secretary has approved the college course of study in mining engineering, and holders of the college diploma or B.Sc. degree in mining are entitled to the exemption authorised by the Coal Mines Act, 1911; the college is on the register of the Institute of Chemistry; and other instances could be given. The governors of the college have succeeded in securing the co-operation of employers. The calendar contains a long list of firms willing to allow a selected number of their apprentices facilities for carrying out a scheme of college study conjoined with practical work; and many Clyde shipping companies have promised to give special consideration to applications for employment from men who have gone through the college course in navigation. The work of great technical colleges like this institution is of vital national importance, and it may be hoped it will receive from the State the recognition it deserves.

THE acting registrar of the University of Durham has sent us a list of the members of the staff of the colleges of the university now serving with H.M. Forces to supplement the lists given in NATURE of July 15 and in other issues. The list includes fifty-five names, twenty of which are of members of the staff of the College of Medicine, Newcastle. We give the names only of members of the scientific staff on active service. *Durham Division*:—P. A. Brown, lecturer in economics, 2nd Lieut. 13th D.L.I.; F. C. H. Carpenter, lecturer in astronomy and observer, Lieut. 8th D.L.I. *Newcastle Division* (*Armstrong College*):—J. Gallon, prize demonstrator in mining, 2nd Lieut. R.F.A.; F. C. Garrett, lecturer in chemistry, Lt.-Col. N. Cyclists; A. A. Hall, assistant lecturer in agricultural chemistry, Lieut. 5th N.F.; H. M. Hallsworth, professor of economics, 2nd Lieut. O.T.C.; T. H. Havelock, professor of applied mathematics and mathematical physics, 2nd Lieut. O.T.C.; W. B. Little, instructor in horticulture, 2nd Lieut. 9th D.L.I.; H. Morris-Airey, lecturer in physics, Lieut. R.N.V.R.; J. Morrow, lecturer in engineering, Major, O.C., O.T.C.; A. D. Peacock, lecturer in zoology, Sergt. R.A.M.C.; J. H. Poulton, prize demonstrator in physics, Sergt. 9th N.F.; J. W. Ramsbottom, lecturer in commercial and industrial economics, Lieut. 20th Manchester Regt.; J. Small, demonstrator in botany, Corpl. R.A.M.C.; L. A. Thompson, lecturer in agricultural surveying, Lieut. 7th D.L.I.; L. M. Thompson, prize demonstrator in geology, 2nd Lieut. 11th N. Staffs.; T. Whitehead, assistant lecturer in agricultural and forest botany, Capt. O.T.C.; D. Woolacott, lecturer in geology, 2nd Lieut. O.T.C.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 6.—M. Camille Jordan in the chair.—A. **Lacroix**: A new type of alkaline granitic rock containing a eucolite. This rock was found at Ampasindava (Madagascar), and belongs to the eudialyte-eucolite group, containing zirconia (16·4 per cent.), and the oxides of cerium, lanthanum, and didymium (22·5 per cent.).—J. **Boussinesq**: The effect of a gradual contraction in a water main on the pressure in the contracted portion. A mathematical discussion of the Venturi effect.—Charles **Richet**: The stimulating action of magnesium salts on the lactic fermentation. The maximum effect on the lactic fermentation is produced by 12·5 grams per litre of crystallised magnesium chloride, $MgCl_2,6H_2O$, very near to the concentration of the same salt found by P. Delbet to exert the maximum effect on phagocytosis.—Paul **Vuillemin**: The morphological value of the corona of the Amaryllidaceæ.—Pierre **Delbet** and M. **Karajanopoulo**: Cytophylaxy. In the defence of the organism against infection the protection of the blood cells (cytophylaxy) is at least as important as the use of antiseptics, and the present paper gives an account of experimental studies of the action of the various solutions employed in the treatment of wounds on the

living cells of the blood, studies specially aimed at finding out any substance capable of increasing the phagocytic properties of the white corpuscles. Most of the antiseptics in current use reduce the phagocytic power; the best results were obtained with a solution of magnesium chloride containing 12·1 parts per 1000. This solution has a marked effect in increasing phagocytosis.—F. **Baldet**: The helicoidal filaments of the Morehouse comet (1908*c*). The electromagnetic interpretation of the forms of the filaments leads to attributing them to jets of electrons emanating from the nucleus and illuminating the gases of the tail of the comet during their passage.—M. **Auric**: A quadruple series of hexahomologic triangles.—Nicolas **Lipine**: The reduction of the periods of Abelian integrals and a generalisation of Abel's theorem.—B. **Galitzine**: An apparatus for the direct determination of accelerations.—Ed. **Delorme**: The ligature of the external iliac artery.—F. **Bordas** and S. **Bruère**: The action of the ferments of urea in the destruction of organic material.

New South Wales.

Linnean Society, July 28.—Mr. A. G. Hamilton, president, in the chair.—M. **Aurousseau**: Petrological notes. No. 1—Igneous rocks and tuff from the Carboniferous of New South Wales. Eleven rocks are described from three localities in the Hunter River Valley. The mode of origin of the rocks described is not yet settled. From internal evidence, they would appear to be volcanic. But Prof. David has recently met with an interesting section near Wallarobba, showing Martin's Creek andesite strongly intrusive, as a sill, into the Carboniferous sedimentary rocks; and he is of the opinion that sill-structure is more extensively developed in the Carboniferous rocks than has been supposed.—Dr. V. F. **Brotherus** and the Rev. W. W. **Watts**: The mosses of Lord Howe Island. Twenty-two species are described as new, as well as some new varieties, and many new records are given, some of which link up the flora of the island with that of the Northern Pacific. All the species recorded were collected by Mr. Watts in 1911.—G. I. **Playfair**: Fresh-water Algæ of the Lismore District; with an appendix on the algal fungi and Schizomycetes. This paper deals with the algæ and algal fungi collected, for the most part, from lagoons, swamps, rain-water pools, and roadside ditches almost entirely within the boundaries of the city of Lismore, during 1914. The fresh-water forms of the Richmond River, at Lismore, were treated of in a paper published last year. The total number of forms recorded from the river was 305; the corresponding number of the land-forms is 308 (of which 207 are additional to those recorded from the river). As the land-forms were collected over an area of about two miles in diameter, the grand total of 512 may be regarded as indicative of a rich microflora. —A. A. **Hamilton**: Topographical and ecological notes on the flora of the Blue Mountains. This paper deals with the range of the plants to be found on the Blue Mountains, in regard to elevation; and about 400 species are listed. The area selected is that between the Hawkesbury-Nepean and Eskbank, a region which includes the highest and lowest elevations on the mountains. It is shown that King's Tableland is a barrier, east and west, which checks or entirely prevents the ascent or descent of many species.

THE CITIZEN AND THE STATE.

(1) *Morals in Evolution: a Comparative Study in Comparative Ethics.* By Prof. L. T. Hobhouse. Pp. xvi+648. Third edition. (London: Chapman and Hall, Ltd., 1915.) 10s. 6d. net.

(2) *The Natural History of the State: an Introduction to Political Science.* By Prof. H. J. Ford. Pp. viii+188. (Princeton: University Press; London: Oxford University Press, 1915.) 4s. 6d. net.

(3) *Citizens To Be: a Social Study of Health, Wisdom, and Goodness, with Special Reference to Elementary Schools.* By M. L. V. Hughes. Pp. xvii+331. (London: Constable and Co., Ltd., 1915.) 4s. 6d. net.

(1) THE present world-struggle is likely to have among its far-reaching results a modification more or less profound in our concepts of both the bases and the standards of civilisation, of morality as a whole, of the State, and of education. Cultural values are in the crucible. The German point of view in each should not be either ignored or over-estimated; the German theory and practice of *Kultur* in war serves as a critical test and ordeal for Western civilisation generally. We speak of German immoralism and "Prussianism"; the Germans describe our own characteristic methods as hypocrisy and "muddling through." Whether these distinctions, if real, are the same as those between perversion and orthogenesis, autocracy and freedom, is an open question, but we can certainly learn from the enemy the lesson of applying science to every department of civilised life and organisation. And, after all, whatever the ideals of a people, it is doomed to stagnation unless its science is living, and is continuously informing every activity of national life. This may be considered an academic truism by the practical man, who is too often the unscientific man; but a truism is none the worse for being academic, and, if true, deserves a trial. The Germans have had the insight to try it, and they have had extraordinary successes therefrom. If these do not continue, it will be the fault, not of the application of science, but of German character and circumstances.

Some thinkers may have noticed how German crimes against human and international morality, such as the destruction of Louvain and the sinking of the *Lusitania,* have passed into somewhat of oblivion in the consciousness of neutral States and bodies, such as the U.S.A. and the Vatican, with a rapidity directly proportional to that of the immediate indignation which they aroused. It may be argued that this phenomenon is due to the absence of retribution, and the argument would be a significant criticism of world-morality. Prof. Hobhouse, in the new and third edition of his "Morals in Evolution," devotes some five pages to the question of punishment, whereas Prof. Westermarck, in his "Origin and Development of the Moral Ideas," devoted about a quarter of his space to it, roughly speaking, about five hundred pages. The significance of this contrast is perhaps to be found in the fact that the outlook of Prof. Hobhouse is philosophical, from the concept, that of Prof. Westermarck is from emotion. Of course, these views are not mutually exclusive, but most usefully mutually subservient. Prof. Hobhouse has practically rewritten his book, and has incorporated in it the investigations into the culture of the "simpler peoples," carried out by himself and Messrs. Ginsberg and Wheeler. This anthropological research on statistical lines enormously increases the value of the book. As before, the author's broad outlook is eminently sane; if he retains any prejudice, it is Hegelian, but one must have an absolute of some sort.

"That the moral standard of man is based on the character of man . . . is a principle which has been little understood in modern ethics." In order to see the genesis of morality the author goes to instinct. Instinct "is a name for human character as it grows up under the conditions of heredity, and it is from this character, with all the faults and foibles along with the virtues thereof, that the moral judgment issues. Human morality is as blind and imperfect as man himself." Sympathy or desire for reciprocal benefits are only small factors in the growth of morals. Again, though "the conception of the Good is the logical foundation of every rule of action . . . the standard of conduct may be affected by causes which are not ethical in origin, though they may come to have ethical consequences. . . . For example, a magical rite may be prescribed as a duty because it is believed to be efficacious in averting a calamity to one's self, one's family, one's society, as the case may be. If the belief in magic disappears, the performance of the rite will cease to be obligatory, although there may be no change in the current conception of the duties to society, family, or self." In this connection, the author has been very successful in estimating the part in morality played by the body of tradition.

With regard to the development of ethical conceptions, we are "constantly tempted to believe that an animal is guided by clear ideas, while the evidence when all put together goes to prove

that it is moving towards an end without clearly and fully apprehending what that end is. And when we have once grasped the possibility of this pseudo-purposive action, we are tempted to generalise it, and deny intelligent purpose in all cases." So the primitive mind is guided by feelings and impulses which it cannot fully understand, and observers may be misled so far as to assert that this or that tribe is destitute of all conception of right and wrong. From the beginning man has been bound by moral law, and the author finds, throughout, "a recurrence of the common features of ordinary morality, which is not less impressive than the variations." Yet, while "ethical progress is essentially a progress in ethical conceptions, acting through tradition," the question whether, "morally considered, the human breed has in fact improved" is difficult to settle. Here the researches of Freud into the nature of the "unconscious mind" would be in point, but "Morals in Evolution" is mainly a study in morphology. As such it is invaluable.

(2) Hegel argued that the State is the realised ethical idea. It is interesting that Hegel commenced the sequence of ideas of which Treitschke was the most spectacular exponent. Prof. Ford, of Princeton, has made "a detailed survey of connections between biology and politics inferable from the doctrine of Darwinism." He concludes that "the fundamental difference between Man and other mammalia is that he is distinctly a product of social evolution." "Man," as Profs. Geddes and Thomson have observed, "did not make society; society made Man"; "the individual," says Prof. Baldwin, "is the result of refined processes of social differentiation." Prof. Ford's book seems to be a series of lectures, based on appropriate quotations in biology, psychology, and linguistics, to contradict the theory of "individual evolution" so called. The State, as Aristotle said, is prior to the individual; language and social psychoses have helped to make the individual mind. There is a well-defined series of stages in the social organic evolution; phylogenetic theory passes into political science. The evolution of the State and the evolution of the individual mind are two aspects of one process, which starts from the human genius for social life. The chief interest of this view is in the relation between man's biology and psychology, and here the advocates of what Prof. Ford styles "the Social Hypothesis" have to assume a "psychological chasm" between man and the primates. Thus, if man's peculiar development of intelligence accounts for the beginings of a social evolution superior to others, and if his peculiar intelligence is only to be explained by the action of his social evolution, there is a circular argument at the very starting-point of the hypothesis.

(3) In his preface to Miss Hughes's volume Prof. J. H. Muirhead observes that the war will pass judgment on two ideals of education, which are intimately bound up with the theory of the State and with the practice of government and citizenship. In the one there is "the disinterested development of the powers of the individual, to the end of giving him his place in a community of free and equal citizens with an outlook beyond to a world-order of like communities." In the other there is a community "narrowed down to a particular nation and state, carrying with it the regimentation of powers and the subordination of will to the end of its own particular purpose of racial predominance." Miss Hughes argues that the "root causes and the root cures of social evils are educational rather than economic," and she pleads for more of the humanist ideal in our educational system. Our elementary education has been adversely criticised; the author succeeds in pointing out its real merits and in proving many good results it has had upon our citizenship. The problem of the school is the problem of the nation, as the Greeks realised long ago. This enthusiastic teacher perhaps asks too much of the average mentality of the people, but not the least merit of her book is the wealth of practical suggestions which deserve the attention of all interested in education, since they are evidently inspired by a high idealism and based upon personal experience.

A. E. CRAWLEY.

CHEMISTRY AND THE MICROSCOPE.

Elementary Chemical Microscopy. By Prof. E. M. Chamot. Pp. xiii+410. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) 12s. 6d. net.

THIS book forms a welcome addition to the very restricted literature of chemical microscopy. It affords a considerable amount of information concerning the microscope itself, and its special adaptation to the purposes of the chemist and metallurgist. It also places at the disposal of the chemist the data for performing a large number of more or less trustworthy microchemical reactions. One notices immediately, however, a singular omission, that of any reproductions of either drawings or photomicrographs of the crystals produced in these reactions as observed under the microscope. A book on microchemical analysis without any indications other than verbal of the appearances seen under the microscope is surely like the play of "Ham-

let" without the title-rôle. Considering the excellent photomicrographical apparatus now available such an omission is not easy to understand. More than twenty years ago the reviewer prepared and showed to his students in the form of lantern slides numerous photomicrographs of the crystalline products of chemical reactions. The book of Haushofer (which does not appear to be mentioned at all by Prof. Chamot), published so long ago as 1885, although faulty in many respects, contained a large number of reproductions of careful drawings of the appearances on the microslip, and the later work of Behrens was also well illustrated in a similar manner.

Another defect obvious to British readers is the very slight mention of, or even complete omission of any reference to, much of the important work achieved by British workers in this domain, especially as regards instruments. For instance, the splendid crystallographic microscopes constructed in London by Swift are ignored, although, after using almost all the Continental microscopes, the reviewer considers no instrument can compare for efficiency or elegance with the later forms of the Dick microscope as made by Swift. Such omissions, however, are not at all uncommon in the recent books and memoirs of United States authors. For example, Prof. F. E. Wright, in a recent memoir on "A New Crystal-grinding Goniometer," an instrument for preparing accurately orientated surfaces on crystals, while making considerable reference to very inferior German apparatus, merely makes a footnote reference to the refined, rigidly stable, very efficient, and much more complete instrument for this purpose constructed long ago by Messrs. Troughton and Simms for the reviewer, and with which the thousands of section-plates and prisms have been prepared for his prolonged work on the sulphates and selenates and numerous double salts. Perhaps the lessons of the war will enable our cousins in the United States to appreciate more fully the important pioneer work in science done in this country, and to be less ready to accept the much more widely advertised German work as being alone worthy of consideration.

When such defects as have been referred to are discounted, a very valuable aid to chemical microscopy will be afforded by Prof. Chamot's book. One of the most interesting chapters is one on ultra-microscopes. It is shown that the ultra-microscope renders visible particles so minute that their diameters may be only slightly greater than the half-wave-length of the light employed, on the principle of the "Tyndall effect," that which is evident in the dust scintillations (diffractions) of a beam of light passing through an orifice into a darkened room. Good illustrations and explanations are given of the Cotton and Mouton, Cardioid, and Zsigmondy ultra-microscopes, the Jentsch ultra-condenser, and the slit ultra-microscope. There is, moreover, a good chapter on the determination of index of refraction by means of the microscope, and also one on attempts at quantitative analysis by the same instrument, including an account of the Barger method of determining molecular weights by micrometric measurement.

The small amount of crystallography, about a dozen pages, is both antiquated and not always accurate; no student could possibly obtain a true idea of the subject without previous or further study. In the preface Prof. Chamot states that his book is intended for students who have passed through a course in crystallography. If there should be many such happy students in the United States they are much more fortunate than their British cousins. Indeed this book only adds one more to the many examples for the very urgent need, both in America and in this country, for the provision of efficient instruction in a subject which is now an essential one to the correct understanding of either chemistry, physics, metallurgy, or any of their many specialised ramifications.

A. E. H. Tutton.

MATHEMATICAL THEORY AND PHYSICS.

(1) *The Mathematical Analysis of Electrical and Optical Wave-Motion on the Basis of Maxwell's Equations.* By Dr. H. Bateman. Pp. vi + 159. (Cambridge: At the University Press, 1915.) Price 7s. 6d. net.

(2) *Homogeneous Linear Substitutions.* By Prof. H. Hilton. Pp. 184. (Oxford: At the Clarendon Press, 1914.) Price 12s. 6d. net.

ORIGINAL, and in fact fundamental, work in mathematics proceeds very rapidly in these days, and in so many departments, that even the expert mathematician frequently complains that it is impossible to keep pace with any but a restricted field. In these circumstances, we can well imagine the position of the unfortunate student who wishes to do mathematical work of a post-graduate nature, and even knows where his inclinations lie, but is appalled by the difficulty of discovering the present condition of any branch of the subject. There is room at present for many volumes which shall fulfil one or more of three main functions—collect together the fragments of a fundamentally important body of theory from their hiding-places in periodicals and text-books on other subjects, give the student exhaustive references to and criti-

cisms of the necessary literature, and specifically indicate the problems which are now awaiting solution. If only because they discharge these functions in two departments of mathematics which, in the opinion of the present writer, are the most difficult of approach by the student, the two volumes now under review have made a most welcome and timely appearance.

(1) The subject dealt with by Dr. Bateman is of very recent growth as such, and is of nearly equal interest to the pure mathematician and the physicist. The references to the workers in this department are sufficient to indicate this fact, and yet the author has been singularly successful in his effort to make the work intelligible to readers who lack a somewhat extended mathematical equipment. Several other branches of modern electrical theory are large enough to need a text-book of their own, such as the Principle of Relativity, and these branches, already provided for, the author does not touch in detail. In fact, the scope of the work is limited to such developments of the electro-magnetic theory as are directly concerned with the solution of the equation of wave motion—the "boundary problems" of the physicist. The theories of potential problems, the scattering and diffraction of waves by obstacles of various forms, the pressure of radiation, electrical vibrations on variously shaped bodies, are typical examples of problems which are admirably reviewed and discussed, not only from the strictly mathematical viewpoint, but with reference to the physical implications of the results. For example, such problems as the tails of comets, wireless telegraphy, and the residual blue of the sky, come within the scope of the volume, although the author is sometimes compelled by considerations of space to give only the general outlines, with the necessary references to enable the reader to pursue the subject. An excellent account of the theory of the various mathematical functions which are necessary is given when occasion arises, without, however, the existence theorems which would render the work unwieldy.

Perhaps the most interesting part of the book is at the end, where the question of possible structure in the æther is discussed. It is sufficient to say that the greater part of the work is Dr. Bateman's own, and the reader is assured of an authoritative treatment of a very fascinating problem. References are exhaustive throughout the book, which fills all the three needs specified in our first paragraph,

(2) The subject of Prof. Hilton's work has a more restricted appeal, and is still to a great extent a matter for the pure mathematician. But recently it has come into prominence in connection with electrical theory, and the appeal is widening. Prof. Hilton has in any case rendered signal service by collecting together, into a connected body of attractive theory, the branch of mathematics which has hitherto been most scattered, or only treated casually as a particular case of more general theory. He confines his treatment to those properties of substitutions which do not depend on "groups," and all such properties which are vital to the Theory of Groups, and the theories of Bilinear Forms and Invariant-Factors receive a satisfactory and connected account in this volume. The discussion of substitutions the determinant of which does not vanish is very complete, and those with a non-zero determinant are sufficiently introduced to the student. Important applications of the work are indicated, the examples are numerous, well graded, and very suitably selected, and there are very few misprints. A student who uses Prof. Hilton's book will find the subject very attractive and easy to assimilate. It should find a place in every college library.

The book is issued by the Clarendon Press, and Dr. Bateman's by the Cambridge University Press. Each volume maintains the best traditions of the series to which it belongs.

OUR BOOKSHELF.

La Science Allemande. By Prof. P. Duhem. Pp. 143. (Paris: A. Hermann et Fils, 1915.)

PROF. PIERRE DUHEM, member of the Institute, has printed four lectures which he gave to students at the University of Bordeaux. Their general aim was to deliver the minds of his hearers from subservience to German thought, and they certainly make for fresh air. The first deals with mathematics and philosophy, and its conclusion is that an excessive fondness for deductive method and a contempt for common sense have made intellectual Germany like the house of Chrysale, whence reasoning drove forth reason. Hegel's axiom as to the identity of contradictories is compared to that of Nicolas of Cues, often called the *cardinalis teutonicus*, that the maximum is always identical with the minimum. But this is surely playing to the gallery. The second lecture is devoted to the experimental sciences, and includes an interesting sketch of Pasteur's trial and error methods, a denunciation of Haeckel, and an assurance that Fabre's fine work has left us with scarcely more than the débris of the Darwinian theory. The exaggeration and misunderstanding involved in the last statement show us that the illustrious author has his obfuscating prejudices like the rest of us.

The best part of this lecture is its illustration of "*l'esprit de finesse*" in French science. The third lecture is on the historical sciences, and is full of righteous anger. It illustrates the

writing of history under the conception of "Deutschland über alles." And not only the writing of history, for it seems that German editions of Cæsar's Commentaries have been subjected to surgical treatment to make them conformable with the axiom. It is not to be supposed that Prof. Duhem has not respect for giants like Leibniz and Gauss; indeed, in the fourth lecture and the appendix, he gives (more philosophically than in the rest of the book) careful appreciation of the geometrical spirit which is at once the strength and the weakness of German science. Of this geometrical spirit English science is all but destitute; its strength is in intuition. The characteristic French qualities are order and clearness, and *l'esprit de finesse*; and each has much to learn from the others.

Mineral Resources of Minas Geraes (Brazil). By A. F. Calvert. Pp. xvi+100+127 plates. (London: E. and F. N. Spon, Ltd.; New York: Spon and Chamberlain, 1915.) Price 6*s*. net.

THIS little volume contains a eulogy of the mineral wealth of the famous State of Minas Geraes, the importance and value of which have long been well known to all who have studied, however superficially, the distribution of the world's mineral resources. The author appears to have searched diligently all available records of Brazilian mining and has evidently read widely and extensively; it is only a pity that he did not supplement his want of knowledge of technical matters by getting some competent mining engineer to revise his proof sheets. This would have saved him from repeating such a foolish criticism as that of Sir Richard Burton upon the shortcomings of the Brazilian miner:—"The Davy and the Geordie were equally unknown to him," the mines referred to being gold mines (!); it would have prevented him from persistently writing "phosphorous" instead of "phosphorus"; it would have most certainly corrected his version of the reports of Baron von Eschwege, from which it seems that the author is unaware that the German equivalent of "blast furnace" is "Hochofen," and that "high furnace" is a phrase that conveys no meaning to the British smelter.

Perhaps the most interesting sentence in the book is one in the preface, where the author summarises the causes that have led to the poor results obtained in Brazil, as a rule, from such great natural resources; he enumerates them as follows:—"Liberation of the slave workers, bad legislation and exorbitant taxation, lack of railway communication, political unrest and financial instability, and the incompetence and dishonesty that have attended the exploitation of the mines and the management of the companies that have been formed to work them," and goes on to point out that in his opinion these drawbacks are being steadily removed. Most British capitalists who have had experience of extensive business operations in Brazil would be disposed to add several very significant items to the above list, not the least important of which would be the rapid fluctuations in the rate of exchange.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Magnetic Measurements.

WITH reference to the very kindly review in NATURE of July 29 of "Electrical Instruments in Theory and Practice," by Mr. U. A. Oschwald and myself, your reviewer takes exception to the suggestion on p. 32 and elsewhere that "in view of its great simplicity the method of testing by the magnetometer ought to be more used than at present."

The reason urged for the rejection of magnetometer methods is that disturbances from neighbouring current-carrying conductors would render it useless, and presumably ballistic, or other methods should be used instead.

I wish to point out on behalf of Mr. Oschwald and myself that we did not suggest the adoption of magnetometer methods in any haphazard way. Both of us have had considerable experience of magnetic work, and the suggestion was made for the following reasons

(1) In ballistic work, if a Thomson moving needle galvanometer is used, as is frequently the case, the same sources of error are present.

(2) No ballistic galvanometer can be calibrated very accurately at present. The values of the constant as determined by Messrs. Hadfield and Hopkinson (Journal Inst. Electrical Engineers, vol. xliv., p. 270) by condenser, standard field, and steady deflection, differ amongst themselves by about 1 per cent.; and there are generally other sources of error in magnetic work.

Now, when electric light wires are laid in a building, the flow and return wires are generally close together in casing, or iron tubing, so that the effect with any reasonable precautions is *less* than 1 per cent. Hence the method is practically equal to the ballistic one, so far as accuracy is concerned

Again, for rapidly *comparing* specimens of iron by the zero method, the objection vanishes, and there is nothing to approach the magnetometer for this purpose.

In my opinion, the ballistic galvanometer is a considerably overrated instrument for this purpose, due possibly to the fact that errors in its constant are conveniently forgotten in the course of research.

Apart altogether from accuracy, there is the outstanding feature of the simple magnetometer, viz. that it measures directly the forces we are dealing with, whereas the ballistic method depends on measuring another quantity altogether. I think I am not wrong in hoping that the magnetometer will be partially restored to its ancient position as the premier magnetic testing instrument.

W. H. F. MURDOCH.

September 3.

WITH reference to Mr. Murdoch's letter on the magnetometer method of testing iron, I described it as an admirable method under suitable conditions. I tried the method about three years ago in my laboratory, which is close to a track return tramway line, and had great trouble with it owing to zero fluctuations. The same difficulty has been found in other laboratories close by, where instruments with very weak magnetic control have been set up. I did not take exception to the suggestion that the

magnetometer method might be used more than it is at present *under suitable conditions*; I wished to direct attention to its practical limitations.

THE REVIEWER.

Nodules on the Intermediate Bladderwort.

I RECENTLY had an opportunity of examining living specimens of a very rare British plant, the intermediate bladderwort (*Utricularia intermedia*), and found that the leaf-bearing stems ended in a solitary terminal knob or nodule, the largest being the size of a small peppercorn. What are these knobs? Are they autumn plant-buds that will ultimately grow into plants? This seems to me a possible solution; but (my edition of) Bentham does not mention that the plant propagates itself in this way, nor are the knobs figured in the companion volume of illustrations by Fitch and Smith.

HAROLD EVANS.

Llanishen, Cardiff, September 17.

NOTES ON STELLAR CLASSIFICATION. III.

IN the year 1890 a photographic study of the spectra of stars was commenced by me at the Solar Physics Observatory at Kensington. The object of the investigation was not so much to make a spectroscopic survey of the stars generally as to examine with considerable dispersion the spectra of the brighter individual stars. Up to the end of the year 1900 there had been accumulated a large number of spectra, a catalogue of which was published in the year 1902. This contained 470 of the brighter stars.

In this catalogue the stars were classified according to their spectra after a minute inquiry of the lines due to each of the chemical "elements" involved.

The spectra of 105 of these 470 stars were photographed by Dr. F. McClean at the Cape Observatory.

Details of this classification were given in the publication above mentioned, but a brief summary may here be given. The stars were arranged in two main groups, one in which the stars were getting hotter ("hotting"), and the other in which they were cooling. The differentiation of these two groups was based, not only on their chemistry, but on other differences observed on the two arms of a "temperature curve."

On the temperature curve the stars increasing their temperature were located on the left-hand branch or ascending arm of the curve, and the cooling stars on the right or descending arm. The stars of the highest temperature were located at the apex of the curve.

The two main divisions of stars, *i.e.* those getting hotter and those getting colder, were each classified according to their chemistry and placed at their respective levels on each side of the temperature curve. At equal levels on each arm the stars were considered to be of the same temperature, each group being designated by a name derived generally from that of the "type star" which had been selected to represent that group.

Further experience with this method of stellar classification led to the detection of criteria which have suggested the interpolation of additional groups, and those have now been embodied in the general scheme as given below representing the classification in use at present, and to it has been added the Harvard scheme of classification of the type stars employed by me.

The main routine work at the Hill Observatory at Sidmouth, since the McClean telescope was brought into use in September, 1913, has been a spectroscopic survey of all stars down to the fifth magnitude other than those published in the above-mentioned catalogue; incidentally the spectra of a number of stars fainter than magnitude five have also been photographed.

This programme of work is especially fitting for this observatory, because the same instrument is in use which Dr. Frank McClean employed in his spectroscopic survey of stars equal to or brighter than magnitude 3·5, the telescope having been presented to the observatory by his son, Frank Kennedy McClean.

The McClean instrument consists of an equatorially mounted twin-telescope with apertures of 12 and 10 inches, and focal lengths of 134 and 150 inches respectively. The former is fitted with an objective prism of 12 inches aperture and 20° angle, and is mounted in a metal frame in such a way that it may be moved clear of the objective. In the focal plane is placed a camera fitted with a swing back by Messrs. Hilger. This carries a plate-holder for plates $6\frac{1}{2} \times 4\frac{3}{4}$, but an adapter has been inserted to carry plates $4\frac{1}{4} \times 3\frac{1}{4}$ which are in use. The dispersion on the photographic plate between K and $H\beta$ is equal to 28 mm. or 927 Ångström units.

The telescope, built by Sir Howard Grubb, of Dublin, is driven by means of falling weights, and is fitted with electric control movements regulated by an electric pendulum. The governor is of the heavy ring pattern, and is adjusted by means of a cam. The declination circle is electrically illuminated, and viewed with the aid of one of two reading telescopes from the camera end. In addition to two finders of 4-inch and 2-inch aperture fitted to the 10-inch tube, a 3-inch finder deviated to the angle of the prism has been specially attached to the tube of the 12-inch; this serves the purpose of observing the amount of

clock rate and for "following" in the case of photographing the spectrum of a comet.

In order to obtain a serviceable width and the necessary density to the spectra, a rate of acceleration or retardation is given to the driving clock. This rate depends on the magnitude of the star in question, its type of spectrum, and its declination. The adjustment for rate is accomplished by regulating the speed of the governor ring by means of the cam mentioned above, the indicator being set to readings which have been derived from previous photographs.

The McClean telescope is mounted on three concrete pillars in a building with a circular concrete-block wall, internal diameter of 18 ft., on which is a hemispherical dome made of wood and covered with rubberoid. The wall is double—that is, has an air space in order to prevent rapid changes of temperature of the air in the dome. The dome rests on iron wheels running on a circular rail fixed to the upper part of the wall, and is easily revolved by hand by means of an endless rope round a grooved pulley fixed to the axis of one of the wheels. The shutters, also operated by hand, are made in two sections and run on rails at their upper and lower extremities; when open, a clear view of the zenith is obtained.

All the electric connections for the telescope and lighting purposes and for the driving-clock wire are led in a trough into an annexe in which are placed the electric pendulum, small accumulators, dark room, etc.

The building is situated on the top of Salcombe Hill to the east of Sidmouth; it is 580 ft. above sea-level, and commands an uninterrupted view of the horizon in every direction.

Since the instrument was first brought into use in September, 1913, the site has been found to have all the excellent observing conditions that were anticipated.

Smoke, mist, artificial-light glare are conspicuous by their absence, and on only one occasion has high wind in a clear sky prevented observation. The hill-top is often clear when the adjacent valley is filled with mist or cloud. Cloud on the top is rare.

The purity of the sky on almost all occasions when free from clouds is extremely advantageous for photographic observations. At South Kensington such clear, dark skies were extremely rare, and then only one or two hours in the early morning were at all comparable with the conditions here. The excellence of the atmospheric conditions is well shown by the extension of the spectra into the ultra-violet. A spectrogram of α Cygni taken with the 9-in. Henry prismatic camera shows the hydrogen series down to H_ω (λ 3667·8), *i.e.* twenty-three hydrogen lines on the one plate. The most refrangible hydrogen line recorded in the South Kensington reduction of the spectrum of α Cygni was H_θ (λ 3798). It may also be mentioned that the southern stars α Columbæ (dec. $-34°\ 8'$) and λ Scorpionis (dec. $-37°\ 2'$) have been seen with the naked eye. The steadiness of the image is normally greater than at South Kensington, and long exposures on faint stars give spectra showing definition of a very satisfactory character.

The working list prepared for use with the 12-in. McClean instrument contains all the stars of the Harvard revised photometry of magnitudes fainter than 4·0 and brighter than 5·0 to the north of dec. $-15°$ which were not included in the catalogue of 470 brighter stars compiled at South Kensington. For these stars exposures of twenty minutes to one hour, according to magnitude and type, are usually amply sufficient to yield spectrograms of sufficient width and density to exhibit enough detail for the purpose of classification. Neighbouring stars fainter even than 6·0 magnitude are sometimes satisfactorily recorded.

A catalogue of the stars the spectra of which have been photographed and classified since 1913 at the Hill Observatory has been prepared; it contains 354 stars. The designations, positions for 1900, magnitudes, and Harvard classification have been taken from the Revised Harvard Catalogue (Annals of the Astronomical Observatory of Harvard College, vol. iv.). In the last column of the table is given the equivalent Kensington classification. The small letters *h*, *c*, and *a* indicate whether the star is increasing its temperature (hotting) (*h*), decreasing its temperature (cooling) (*c*), or at the apex (*a*) of the temperature curve or about the condition of being most hot. The letter (*p*) denotes that there is some peculiarity about the spectrum.

These small letters will save references to the groups in my classification in the case of those inquirers chiefly interested in temperatures. They also show that the Harvard classification includes both classes of stars under the same designation in the other cases.

Before the war Lieut. Lockyer, R.N.V.R., and Mr. Johnson and Mr. Goodson were the assistants engaged in photographing and classifying the spectra. Since Lieut. Lockyer and Mr. Johnson took up their military duties, their work has been carried on by Mr. Goodson.

NORMAN LOCKYER.

THE ATTACKS OF BIRDS UPON FRUIT.

UNDER the heading of "The Ravages of Birds" a correspondence has arisen in the *Times* which is apt to mislead both the general public and fruit-growers on a subject already overburdened with misrepresentation and error.

It is suggested by one correspondent that there are two simple methods for preventing the attacks of birds upon fruit, viz., (i) provision of drinking water, (ii) provision of food to entice the birds away from the fruit. That there may be a scarcity of water in some districts is quite possible, but at the time when the missel thrush, blackbird, blackcap, bullfinch, etc., attack fruit there is an abundance of animal food in the form of insect larvæ, insects, worms, slugs, snails, etc., in addition to wild fruits and seeds. Further, if a few of these fruit-eating birds are shot, and the

stomach contents examined, it is surprising how little fruit-pulp is found. Again, if blackbirds are kept in confinement and fed on similar ripe fruit very little is consumed.

Careful observation and experiment have shown that in most cases where ripe fruit is attacked it is not due to a scarcity of food, and that very much more fruit is damaged than eaten. In different parts of the United States it has been found that the provision in orchards of water has considerably lessened the damage by birds to the fruit.

Mr. G. F. Burgess, another correspondent, asks, "If the birds need water, why provide food? If it is food they want, why provide water? It is quite possible," he continues, "that the birds acquired the 'fruit habit' in times of drought, but the habit is now so well established that the damage goes on in wet and dry seasons alike." This brings us much nearer the actual truth. A supply of water may keep young birds away from the fruit in times of drought, but once a bird acquires the fruit-eating habit, experience shows that nothing will change it.

This change of habit in the nature of the food opens a big question, and one around which much controversial matter ranges, but where cases have been subjected to careful investigation by competent workers one striking fact has been brought out, viz., that the particular species of bird or birds had been allowed to increase unduly, and is now too plentiful. This has been proved in the case of the cereal-feeding habit of the rook,[1] and the fruit-eating habit of the blackbird and missel thrush.

It seems surprising that, in a country where the question of producing the maximum amount of home-grown food is one of vital importance, so many economic problems related thereto have been almost entirely neglected. We are offering protection to certain injurious wild birds and permitting other beneficial species to be wantonly destroyed, with the result that food to the value of tens of thousands of pounds sterling is annually destroyed. That the same thing is taking place in connection with our fisheries there is good reason to believe.

In other countries the State has made provision for systematic and continued investigation on the subject, much to its material benefit, but as a writer has recently very pertinently stated, "In the matter of economic ornithology we in England are disgracefully behind the times; the Board of Agriculture seemingly prefers to leave this matter to private enterprise, or to deal with the matter in such a perfunctory manner as to be positively ridiculous, making us the laughing-stock of the nations."[2] In the past the want of financial means has been the excuse, but the present apathy can scarcely be due to that cause, seeing the manner in which huge sums are being used out of the Development Grant for far less important purposes.

WALTER E. COLLINGE.

1 "The Food of Some British Wild Birds." (London, 1913.)
2 *Ann. and Mag. Nat. Hist.*, 1908 (s. 8), vol. ii., p. 132.

NOTES.

AMONG those who were on board the *Royal Edward* when she was torpedoed and sunk in the Ægean Sea was Capt. Charles Bertram Marshall. When last seen he was standing on the deck giving orders to his men to keep cool; and he seems to have died as he had lived, a brave, generous, and unselfish man. Although Capt. Marshall had no intention of devoting himself to purely scientific pursuits, he belonged to that too rare class of medical men who, before embarking upon the practice of their profession, endeavour to obtain a thorough all-round training in the ancillary sciences and experience in original research. In addition to the customary series of hospital appointments, Dr. Marshall held a demonstratorship in anatomy in Manchester University, and carried out a successful investigation in reference to the movements of the stomach and the chemistry of the digestive processes, for which he received the M.D. degree with commendation. He was a man of exceptional ability and charm of character, and he gave promise of accomplishing much in the advancement of the science of medicine.

WE regret to see the announcement that Lieut. J. A. Dixon was killed at the Dardanelles on August 9. After a first season's work in Nubia, he took part in the expeditions sent to Abydos in Upper Egypt by the Egypt Exploration Fund in the winters 1909–10 and 1910–11, in the capacity of draughtsman and assistant excavator. The illustrations of the volumes dealing with those expeditions are a sufficient testimony to the amount and quality of his work. His ambition, however, was to make a name for himself in the field of copying in water colours the scenes which adorn the rock tombs of Thebes, and his first efforts in this direction had met with considerable success. In the desert camp, where the qualities of a man are tried to the utmost, he was a keen worker and a bright and frank companion, generous to the last degree. He loved Egypt and everything in it, from the luxury of a Cairo hotel to the discomfort of the excavator's camp. His treatment of natives was ideal: sympathetic, just and friendly, and yet with that background of firmness which too many Europeans lack, but which is, in truth, the only passport to the respect and admiration of the Arab. Since 1912 he had been connected with the expeditions of Mr. Wellcome in the Sudan, but there is little doubt that his heart was in Egypt proper, and that, had he lived, he would have contrived to return to his painting among the Theban tombs.

MR. CLAUDE GRAHAME-WHITE and Mr. Harry Harper contribute to the *Fortnightly Review* for September an interesting account of "Zeppelin Airships: their Record in the War." It is refreshing to find an article on aircraft, especially Zeppelin airships, which is not full of that nonsense which the present conflict has inspired in overflowing measure. A highly-complex technical problem such as the airship presents is not readily made clear to the lay mind, and the authors of this article give only slight space to a discussion of technical questions of construction,

confining themselves to a consideration chiefly of the Zeppelin airship as a weapon of war. This aspect, while fascinating to the layman, is to the average technical mind much the least attractive avenue of speculation and inquiry, seeing that difficulties which can be comfortably overcome by a peace-airship are quite insuperable in one for use in offensive operations. It is easy to conceive airships in the future having sufficient strength to withstand all ordinary weather, but it is frankly impossible to conceive an airship that will stand any chance of surviving the anti-aircraft gunnery of the immediate future, provided it can be seen by the gunner. For offensive operations of value, the airship cannot avoid being in sight of the ground, and consequently it will be unable to undertake such operations. All war, however, does not consist of fighting, and there is plenty of scope for the excellent qualities of lighter-than-air aircraft in reconnaissance and so forth. It is a pity that so much ill-informed matter has been written about Zeppelins as aerial "Dreadnoughts"—in point of fact, there is very little else they can do when attacked but run away. The authors of this article are to be congratulated on the sane aspect of the case they have presented.

DURING the recent meeting of the British Association, the members were invited by the Manchester Literary and Philosophical Society to visit its house in George Street, Manchester. Particular interest is attached to this house, since it was for many years the scene of the labours of John Dalton, and contains a collection of his apparatus, lecture diagrams, notebooks, and manuscripts. This collection, along with other treasures belonging to the society, was set out for exhibition, and was described to the visitors by Prof. W. W. Haldane Gee. The apparatus, which is in a remarkably good state of preservation, includes a valuable collection of instruments used by Dalton in his researches and in his lectures on chemistry, heat, light, sound, electricity, mechanics, meteorology, and astronomy. The diagrams, many of which refer to the atomic theory, are those used by Dalton to illustrate his lectures. They are described by Prof. W. W. Haldane Gee, Dr. H. F. Coward, and Dr. Arthur Harden in a "Memoir" of the society. The notebooks, manuscripts, etc., which are also described in the "Memoir," show the nature and scope of Dalton's lectures, and give some interesting information about his expenses. The Manchester Literary and Philosophical Society is one of the oldest scientific institutions in the world, and has held its meetings in the house in George Street for nearly 120 years. The list of its past presidents includes such illustrious names as James Prescott Joule, John Dalton, Sir William Fairbairn, and Sir Henry Roscoe. The society possesses a very valuable library, which includes a collection of the publications of almost all the important scientific societies from their foundation.

A TABLET was unveiled on September 18 in Cheltenham College Chapel, and a life-size portrait by Mr. Hugh Riviere in the College Library, to the memory of Dr. E. A. Wilson, who perished with Captain Scott in the Antarctic. The late Dr. Wilson was educated at Cheltenham College.

AT the sale by auction of the Amesbury Abbey estate on September 21, the historic monument of Stonehenge was purchased for 6600*l.* by a local landowner, Mr. C. H. E. Chubb, of Bemerton Lodge, Salisbury. The estate came into the market in consequence of the deaths of Sir Edmund Antrobus and of his only son, who was killed in action last October. As Stonehenge is under the protection of the Ancient Monuments Act, no steps can be taken by the owner to alter or remove any parts of this remarkable relic of antiquity.

ACCORDING to the *Morning Post* correspondent at Christiania, a telegram from Archangel to the Foreign Office there states that the *Eclipse* Expedition, under Commander Sverdrup, has returned, and that all on board are safe Commander Sverdrup left Christiania on July 15, 1914, at the request of the Russian Government, with the object of seeking for traces of the Russian expeditions under Brusiloff and Rusanoff, which had been lost in the Polar regions. He wintered in the western portion of the Taimyr Peninsula, and engaged in exploration work during the succeeding summer, but found no traces of the missing Russians.

SIR FREDERICK DONALDSON, Chief Superintendent of Ordnance Factories, has been appointed to act for the time being as technical adviser to the Ministry of Munitions. In the meantime, arrangements have been made for Mr. V. L. Raven, chief mechanical engineer of the North-Eastern Railway, whose services have been temporarily placed at the disposal of the Minister of Munitions by the board of directors, to perform the duties of acting chief superintendent of the Royal Ordnance Factories, Woolwich.

THE Minister of Munitions of War, with the concurrence of the Home Secretary, has appointed a committee to consider and advise on questions of industrial fatigue, hours of labour, and other matters affecting the personal health and physical efficiency of workers in munition factories and workshops. The committee is constituted as follows:—Sir George Newman (chairman); Sir Thomas Barlow, Bt., K.C.V.O., F.R.S.; G. Bellhouse; Prof. A. E. Boycott, F.R.S.; J. R. Clynes, M.P.; E. L. Collis; Dr. W. M. Fletcher, F.R.S.; Prof. Leonard E. Hill, F.R.S.; Samuel Osborn, J.P., Sheffield; Miss R. E. Squire, and Mrs. H. J. Tennant. Mr. E. H. Pelham has been appointed secretary to the committee; and all communications should be addressed to him at the offices of the Board of Education, Whitehall, S.W.

THE nature and limitations of portable fire-extinguishers were dealt with in articles in NATURE of June 3 and July 22. Sir Edward Henry, the Commissioner of Metropolitan Police, has now repeated a warning issued on June 28 that chemical liquid fire extinguishers should not be purchased without a written guarantee that they comply with the specification of the Board of Trade, Office of Works, Metropolitan Police, or some approved fire prevention

committee. Many dry powder fire extinguishers are much advertised. The Commissioner warns the public, as the result of experiments made at his instance, by a competent committee of experts, that no reliance can be placed upon such appliances for effectively controlling fires such as are likely to be caused by bombs—explosive or incendiary. The Commissioner is advised as the result of these experiments that the provision, and prompt and intelligent use, of water or sand or of both in dealing with such outbreaks of fire is the best, simplest, and most economical safeguard.

THE United States National Museum, Washington, has recently obtained the greater part of a fine skeleton of Mastodon from a swampy deposit near Winamac, Indiana. The bones are in a good state of preservation, and when prepared will be mounted for exhibition.

THE eighth number of the *Boletin* of the Sociedad Physis of Buenos Aires, just received, completes the first volume of this publication. The society was founded in 1912 for the promotion and diffusion of natural science in the Argentine Republic, and has met with considerable success. All the published papers record the results of original research, and each part of the journal concludes with a useful series of reviews and notices of writings dealing with the geology, botany, zoology, and anthropology of South America.

DR. J. W. FEWKES, of the U.S. Bureau of Ethnology, has started to continue his exploration of the remarkable ruins in Mesa Verde National Park in south-west Colorado, which are believed to be the work of the ancestors of the modern Pueblo Indians. One of these constructions, known as Spruce Tree House, resembles a gigantic hotel built in a cave, the floor of which is about 50 ft. above the bottom of the canyon, while the roof is 80 ft. high. In some places the rooms occupied three stories, and the building may have accommodated 350 persons. Cliff Palace is nearly three times the size of Spruce Tree House, and, like it, stands in a cave to which access is gained by steps cut in the rock and by ladders. An important part of this structure is a ceremonial chamber entered from a subterranean passage. Here it is believed that the tribal ceremonies were performed. These structures, when fully excavated, will throw much light on the social life, religious and secular rites of this remarkable people.

WE have received a copy of the Madras Agricultural Calendar for the year 1915–16, issued by the Madras Agricultural Department, which contains a series of useful articles on green manuring, cotton and its cultivation, on various veterinary subjects, and on native implements and subjects of value to the small proprietor. The calendar portion gives information about cattle fairs and other matters of native interest, and, by way of introduction, the purpose of the Agricultural Department is fully explained.

THE first number of the Journal of the Botanical Society of South Africa has recently been published under the editorship of Prof. H. H. W. Pearson, hon. director of the National Botanic Gardens, Kirstenbosch. It includes a short notice of the late Lord de Villiers, the first president of the society, to whose interest and influence the establishment of the gardens and the founding of the society was so largely due. An interesting account of former public and private acclimatisation and botanic gardens at the Cape, with an outline of the establishment in 1913 of the National Garden at Kirstenbosch, is also given. It is a matter of regret that this important enterprise seems likely to suffer financially owing to the war, just when funds are so essential for furthering the initial stages of its development. It is to be hoped that the Botanical Society, to the assistance of which the new National Garden owes so much, will continue to bear its share in the responsibility of developing the Garden as generously as in the past, and will be able to enlist many new members to help on the work.

THE Transactions of the Royal Scottish Arboricultural Society, vol. xxix., part ii. (July, 1915), contain several articles dealing with larch, the most interesting being an account of the first-generation hybrids between the Japanese and the European species, which are making astonishingly rapid growth on two estates in Perthshire, where they originated a few years ago. A new species, *Larix olgensis*, from eastern Asia, is described and figured; but it is not considered likely to be of any value for economic planting. Mr. Marshall, who has extensive plantations of larch in the Lake district, gives the results of experiments, which show that the wood of the Japanese larch is considerably inferior in strength to that of the European species, at any rate when young and of a size only big enough for pitprops. The Transactions contain useful notes on various insect and fungus pests. It is satisfactory to learn that new regulations of the Postmaster-General facilitate the purchase of home-grown Scots pine for use as telegraph poles.

THE number of species of Ficus at present known from tropical Africa is 173, and the genus has recently been revised for the "Flora of Tropical Africa" by Mr. Hutchinson. Descriptions of the new species, illustrated in many cases by useful text figures, are given in *Kew Bulletin* No. 7, 1915. Our knowledge of the genus has been increased mainly owing to the collections made by Dr. J. Mildbraed, and to the extensive material sent to Brussels from the Belgian Congo. The genus is broken up into five subgenera; four of these have the bracts of the ostiole of the receptacle spread horizontally across the mouth, so that some of them are visible from the outside; but in the fifth subgenus, Bibracteatæ, containing 73 species, the ostiole from outside looks like a single pore-like slit, as all the bracts are abruptly reflexed and point vertically downwards into the receptacle. The present paper deals mainly with species belonging to this subgenus.

"THE Trees and Shrubs of the Pacific Coast" is the title of an interesting paper by Mr. F. R. S. Balfour, printed in the Journal of the Royal Horticultural Society, vol. xli., part i., August, 1915, which

was delivered as a lecture before the society in April of this year. The paper is illustrated by a number of excellent reproductions of the trees and shrubs mentioned in their native habitats from Vancouver to California. The region near Mount Rainier, discovered by Vancouver in 1792, is the home of many fine conifers, notably *Abies nobilis*, *Thuya gigantea*, Douglas firs, etc., and a number of interesting shrubs, seeds of which were collected by Mr. Balfour. The Siskiyou Mountains, on the borders of S. Oregon and N. California, were also visited in order to see that rare and interesting conifer, *Picea breweriana*, the weeping spruce, of which some excellent photographs are reproduced. Possibly not more than 5000 trees of this species exist in the wild state, but it has now been introduced to Britain, and the young trees are thriving well. The drooping branchlets, some 6–8 ft. long, hang down like those of the weeping willow. The last region described in the paper is the Monterey district of California, the home of those well-known and useful conifers *Pinus insignis* and *Cupressus macrocarpa*. The latter is illustrated by photographs of picturesque old specimens. These trees, the native habitat of which is now a very restricted area, were long ago introduced to Europe, Chile, New Zealand, and the Cape, where they are thriving as in their native country.

Lignum nephriticum, the wood which, infused with water, yields a yellow solution possessing a remarkable blue fluorescence, has been an object of interest ever since it was first brought to Europe from Mexico, soon after the discovery of America. Robert Boyle made a systematic study of the solution in 1663, which may be regarded as the first serious investigation of the phenomenon of fluorescence, but considerable doubt has existed as to the exact scientific identity of the tree yielding the wood. The most recent contribution to the history of *Lignum nephriticum* is published in the Journal of the Washington Academy of Sciences (vol. v., No. 14, August 19, 1915) by Mr. W. E. Safford. He gives the name *Eysenhardtia polystachya* (Ortega), Sargent, to the tree, and states that its botanical identity has remained uncertain until the present time. This statement, however, is scarcely correct, since the tree was referred to the genus Viborquia by Ortega, a name superseded by the later name of Eysenhardtia of Humboldt, Bonpland, and Kunth. These authors correctly named the plant *E. amorphoides* in 1823, and Mr. Safford, following Sargent, merely restores Ortega's old specific name, *Viborquia polystachya*, making *Eysenhardtia amorphoides* a synonym of *E. polystachya*. The story of *Lignum nephriticum*, with an account of its remarkable properties and its synonymy, was set out at some length in the *Kew Bulletin*, 1909, pp. 293–305, by Dr. Stapf, and Mr. Safford adds very little to the account there given. His paper is of value, however, because he reproduces Ortega's original illustration of *Viborquia polystachya* and also a photograph of specimens recently collected at Tamaulipas, Mexico. It was owing to its supposed diuretic properties that the wood of this leguminous tree received the name *Lignum nephriticum*.

We learn with regret that a heavy gale which passed over the island of Dominica caused a considerable amount of damage to the Botanic Garden. About 100 trees, some of large size, were uprooted, and many others are reported to have had their tops blown off or to have been seriously damaged by the loss of branches. Unfortunately, a number of species of rare trees represented in the Garden by only a single specimen have been destroyed. The clearing of the devastated area will be a work of many weeks, and at least a generation must elapse before the Dominica Gardens can be restored to their former interesting and beautiful condition. Some of the lime estates in the island were also badly damaged, not only owing to the loss of crop, but also by the uprooting of a considerable number of trees.

In Bulletin No. 47, issued by the Agricultural Research Institute, Pusa, Mr. Peter Abel describes a tour of the sugar factories in the Bihar district of northern India, made at the invitation of the Indian Government, with the object of advising on the machinery in use and the general management of the plants. Judged by the standard of the West Indies and America, these Indian factories are small, and run on such primitive lines that many of the labour-saving devices generally used in the west are not applicable. The approaches and exits were in most cases badly arranged, resulting in blocks and confusion of the bullock carts delivering cane. As the feeding of the mills is done entirely by hand a great deal of labour could be avoided by the use of suitable derricks for handling the cane, and at the same time give a more regular feed to the mills. The methods of clarification appeared to be capable of considerable improvement, many of the appliances being defective or badly situated for inspection and cleaning. In most of the factories the evaporators and vacuum pans were adequate, but in only two were the crystallisers sufficient in number to ensure the maximum reduction of the sucrose in the molasses. Since the quality of sugar depends to a great extent upon clarification, the inefficiency of this section of the plants is responsible for the inferiority of the average product. One small factory, however, possessing an adequate clarifying and crystallising plant, was producing two sugars of excellent quality. Although the Indian factories do not at present obtain a satisfactory extraction, a few modifications and additions would enable them to obtain results very little behind those of the best works in Java.

The Carnegie Institution of Washington has just published Prof. E. C. Case's fifth contribution to our knowledge of the vertebrate fauna of the Permo-Carboniferous red beds of North America (Publication No. 207). More than half of the work is an exhaustive technical description of the geological formations themselves in all known regions, with numerous quotations from the writings of other authors. The second part is more general, and includes a valuable summary of the results of Prof. Case's own researches. The vertebrate fauna is one of estuaries, swamps, alluvial plains, and open woodlands. Among the fishes, even the sharks have a fresh-water appearance.

All the amphibians are of the usual Labyrinthodont pattern, with a carnivorous dentition. Among the reptiles the teeth are more varied, but hitherto no form has been discovered which can be regarded as purely or even largely herbivorous. Some species must have been powerful carnivores, others may have eaten plants mingled with a main diet of hard-shelled molluscs. In outward shape, according to Prof. Case's numerous restorations, there is monotonous sameness, both among amphibians and reptiles—animals with large head, short neck, ungainly trunk, and weak limbs. The only notable feature is the well-known dorsal crest of Dimetrodon and its allies, produced by the elongation of the neural spines of the backbone. During life, of course, more variety may have been imparted to the different forms by coloration and epidermal structures. Prof. Case concludes that although the earliest of the North American Permo-Carboniferous reptiles are closely related to those found in South Africa, the evolution of the group was different in the two regions. In North America all specialisations seem to have been in the direction of higher reptiles, while in South Africa specialisation was clearly in the direction of mammalia.

THE fifty-third annual report of the Government cinchona plantations and factory in Bengal for the year 1914–15 is a remarkably interesting document, and affords striking evidence of the valuable work unobtrusively carried on by the distinguished botanists who have held the post of superintendent of cinchona cultivation in Bengal. Between 1887 and 1892 enough bark was produced in the plantation at Mungpoo to meet the annual demand, never exceeding 4000 lb., for quinine. By 1905 the demand had risen to 15,000 lb., but the annual yield from plantation bark never reached 9000 lb. of quinine. A new plantation was started at Munsong, the old one improved, the factories enlarged, and a quinologist appointed, with the result that now the annual output of quinine has increased to as much as 50,000 lb. Not only has the quality of the trees planted been greatly improved and the area under cultivation enlarged, but the methods of extraction now employed have raised the average quinine percentage from 2·5 to 4·5. Since 1905 the annual possible harvest has increased from about 300,000 lb. of 2·5 per cent. bark to 1,000,000 lb. of 4·5 per cent. bark, a quantity assured for many years to come; the possible annual output of the factory has increased from 14,000 lb. to more than 50,000 lb. of quinine, its extraction efficiency has been raised from not more than 75 per cent. to 95 per cent. of the possible, while the manufacturing cost of quinine has been reduced from Rs. 9 to a little more than Rs. 5 per lb. Moreover, the quinine reserve has risen from less than 3500 lb. to more than 163,000 lb. When it is remembered that cinchona takes ten years to arrive at maturity, this record of ten years' work must be regarded as a remarkable achievement. The work of reconstruction initiated by Sir David Prain has been most ably carried on by Major Gage, his successor in office, who records his indebtedness to Mr. Shaw, the Government quinologist, and to the managers of the two plantations, Mr. H. F. Green and Mr. P. T. Russell, through whose keen interest and cordial co-operation the success of the undertaking has been rendered possible.

IT has long been suspected that the mutarotation phenomena observed in freshly-prepared solutions of many sugars might be due, not to a direct isomeric change, but to changes involving the formation of one or more intermediate products. Direct evidence in favour of this view is given in a paper by Prof. Irvine and Miss Steele on "The Mechanism of Mutarotation in Aqueous Solution," which appears in the August issue of the Chemical Society's Journal. The curves showing the changes of conductivity and of rotatory power in freshly-prepared aqueous solutions of tetramethylglucose are of the usual simple form; but when the sugar is dissolved in aqueous boric acid the conductivity passes through a maximum at the end of about two hours, whilst the rotatory power shows a well-marked arrest at about the same time. These observations indicate the formation of an intermediate product capable of combining with boric acid. The authors consider that this product is an oxonium hydrate. The conductivity curve gives some indication, however, that the limit of complexity has not yet been reached, and that there may be two intermediate products instead of only one.

Engineering for September 17 has a concluding article on worm-gear in which is contained the discussion on an important paper by Mr. F. W. Lanchester, reprinted in previous articles. The Lanchester worm is of the hollow type, and very careful tests reveal very high and consistent efficiencies. The preservation of the oil film between the surfaces in contact is all-important, and it is possible that the film can be kept better in place with a hollow worm than a parallel one. Mr. Lanchester says that for the purposes of discussion the surfaces in contact in his worm-gear may be represented by ellipses of elongated form. The motion is broadside, and the pressure is continually exerted on a region to which the oil had just previously been squeezed, so that the surface continually floated on an oil film instead of sinking through it. With light pressures this action is not important, but when the pressures exceeded half-ton to one ton per square inch the squeezer action became important. The gear was applied to the Lanchester car in 1897, and had been fitted to every Lanchester car since that date.

THE Manchester Literary and Philosophical Society has published a catalogue of the serial publications in its library. The catalogue has been compiled under the direction of the honorary librarian, Mr. C. L. Barnes, by the librarian, Mr. A. P. Hunt. The total number of current publications at present received by the society is 810; and these, together with a number of serials no longer in progress, have all been dealt with. To facilitate the finding of any individual work, a copious index has been added, in which each town, institution, and title of publication is mentioned separately.

OUR ASTRONOMICAL COLUMN.

THE SUPPOSED NEW COMET.—Ephemeris Circular No. 492 of the *Astronomische Nachrichten* contains a notice from Prof H. Kobold, Kiel, announcing that Prof. Frost has identified the supposed new comet discovered by Mr. J. E. Mellish on September 6 with N.G.C. 2261.

STAR COLOURS.—There are two methods by which the colours of stars are being determined:—(1) the direct method, in which a coarse objective grating is used, and estimates made of the mean effective wave-lengths of the light from the stars; and (2) comparison of the relative intensities of two separate regions of the stellar spectrum. As usually effected, this is an indirect method, based on measures of photographic and visual (or photovisual) magnitudes. Three recent contributions from Mount Wilson Observatory, (*Astrophysical Journal*, vol. xli., No. 1) deal with this subject. In one of these Prof. E. Hertzsprung presents an account of his researches on the stars in the cluster N.G.C. 1647 by the grating method used in conjunction with the 60-in. reflector of the Mount Wilson Observatory. Photometric magnitudes and effective wave-lengths are given for rather more than 200 stars in the cluster. In the case of 44 stars, a comparison of the measures of effective wave-length are compared with a rough classification of the spectrum. Partly from this paper, Mr. F. H. Seares derives data for a comparative study of colour-indices measured indirectly with those obtained by transforming effective wave-lengths. Results for 47 stars of magnitudes between 11·5 and 15 indicate that for this interval the two series of colour-indices show the same increase in mean colour with increasing magnitude. In the remaining paper, Prof. Hertzsprung discusses the mean effective wave-length of a number of absolutely faint stars. Effective wave-lengths show little change for stars of abs. mag. +3 and +8, the values lying between $\lambda\lambda$ 4500–4600. The suggestion is made that the abs. mag. +3, corresponding to a temperature of 3400° abs. for a black body the size of the sun, represents the stage of a cooling star at which relatively dark solid matter begins to form on its surface.

RAIES ULTIMES.—Comte A. de Gramont designates by this term those lines in the spectrum of an element which for any given source of luminescence persist longest as the percentage of the element is reduced. They are thus lines of maximum sensitivity. In a paper lately published (*Ann. Chem.*, vol. iii., May–June, 1915) it is pointed out that the effect of reduction of quantity of substance should not be confounded with diminished exposure in photographing the spectrum. The one operates on the spectrum, the other acts merely on the record. The persistent lines are not identical in the two cases. It appears that in general the vestigial spectrum is not of necessity made up of remnants of the strongest lines of the elements, though, in fact, the *raies ultimes* mostly seem to be either the strongest or among the strongest lines, and they are usually lines which readily reverse. They bear some sort of relationship to the "long" lines employed by Sir Norman Lockyer some forty years ago as criteria to establish the presence of less spectroscopically conspicuous elements in the sun. The paper contains interesting suggestions regarding the energy distribution in line spectra and on the relationship between the *raies ultimes* and the point of maximum radiation.

EARLY NAUTICAL ASTRONOMY.—An address on the beginnings of geographical science, delivered by Sir Clements R. Markham before the Royal Geographical Society on June 10 last (*Geographical Journal*, vol. xlvi., No. 3, September, 1915), contains much extremely interesting information regarding the development of astronomical methods, instruments and tables, employed in navigation during the period of revival of nautical adventure; the period of the first Transatlantic voyage, and the rounding of the Cape of Good Hope. It was, in fact, the efforts of the Portuguese to open up the western coast of Africa, leading seamen into southern waters out of sight of the familiar Polaris, that necessitated the formulation of new methods. A mathematical Junta appointed by King Joâo II. of Portugal (1481–95) triumphed over the difficulties. It now appears that a Jewish royal physician was the leading spirit of the commission, and it was a friend of his, Abraham Zacuto, professor of astronomy at Salamanca, who had ready at hand the requisite tables giving the sun's declination. Lack of space forbids further description here. The lecturer drew largely on the researches of Senhor Joaquim Bensaude, in particular on the latter's work "L'Astronomie nautique au Portugal à l'époque des grandes découvertes," Bern, 1912.

APPROXIMATE DETERMINATION OF PLANETARY LONGITUDE.—In *Knowledge* (August) Prof. Herbert Chatley gives a simplified method of calculating planetary longitudes for elliptic orbits without employing intricate mathematics. The method depends on the assumption, apparently very nearly true, that the difference between uniform circular motion and elliptic is harmonic. It is claimed that the method is capable of giving results to within a few minutes of arc.

THE CANADIAN ARCTIC EXPEDITION.

MR. VILJALMUR STEFANSSON, the Canadian Arctic explorer, whose unexpected safety is announced, contributes his personal narrative of the expedition to Monday's *Daily Chronicle*. He left Alaska in July, 1913, for the Beaufort Sea. Bases were also to be established on Prince Albert Sound and Patrick Island. Mr. Stefansson was accompanied by Dr. Forbes Mackay and Mr. James Murray, of Shackleton's first Antarctic expedition; M. Henri Beuchat, a French anthropologist, who was to study the Eskimo of Bank Land; Mr. W. L. McKinlay and others. Captain Bartlett, of Peary's North Pole expedition, was in charge of the *Karluk*, the main ship of the expedition. Whether or not the *Karluk* could reach Patrick Island and penetrate the Beaufort Sea depended on the prevailing winds. With a persistence of easterlies, which Stefansson hoped for, this would be possible, but otherwise he realised that his plans must be modified.

Early in August, 1913, the *Karluk* was beset in the ice in 147° W., fifteen miles off the shore. In the belief that the ship was firmly frozen in, Stefansson, with three companions, went ashore to hunt towards the end of September. During their absence a strong north-easterly gale broke up the ice and carried the ship away to the west. Passing near the coast firmly beset in the ice the *Karluk* was carried north-westward to 73° N. 162° W. on November 11. Her drift then changed to south-west, and by the end of the year she was sixty miles north-east of Herald Island. Two weeks later the ship was crushed and sank, but not before a quantity of stores had been placed on the ice. Herald Island could not be approached on account of open water, so tracks were made successfully for Wrangell Island. A party of eight, however, including Dr. Mackay, Mr. Murray, and M. Beuchat, who had left the *Karluk* earlier in an attempt to reach

NO. 2395, VOL. 96]

Herald Island, failed to turn up. Captain Bartlett crossed Long Sound and with great difficulty reached the Alaskan coast, which he followed eastward to Emma Harbour, whence a whaler took him to St. Michael. From there a relief ship set out to Wrangell Island and brought back the remaining survivors of the *Karluk*. Three of the party had died on the island, and later search failed to reveal any trace of Dr. Mackay and his party, all of whom probably perished by falling through the ice.

Meanwhile Stefansson had attempted to retrieve the fortunes of the expedition. After a winter in the Mackenzie delta (1913–14), he set out northward over the ice with seven companions, starting from Martin Point, 140° W., on March 22, 1914. Three weeks later the supporting party turned back, bringing news that Stefansson meant to continue northward for at least another fifteen days. A small vessel, the *Polar Bear*, searched for them along the coast of Banks Land last year, but found no trace, and it was generally supposed that Stefansson and his party had perished until the news came last week. Travelling over the ice, and often drifting with it, the party reached 73° N., 140° W. Stefansson then decided to turn eastward, and ninety days after leaving Cape Martin landed on Banks Island, thirty miles south of Cape Alfred. From there he went south to Cape Kellat and met his supply ship. In the winter a four-hundred mile sledge journey to Victoria Island failed to reveal Eskimo. In February this year Stefansson, with three companions, set out northward *viâ* Cape Alfred to Patrick Island, and up its eastern side to Cape McClintock. To the north-east they discovered an extensive new land rising to a height of 2000 ft. The return journey was along the west coast of Melville Island, across McClure Strait, to the Bay of Mercy, and thence across Banks Island to Cape Kellat. From there Stefansson reached Herschell Island in the *Polar Bear*. Throughout his travels he lived chiefly on caribou, bears and seals, and suffered no want. He has since returned to Banks Island, and next year intends to explore his new land, and to make a journey over the Beaufort Sea. Surveys were made of the lands visited, and the work of Sir Robert McClure amplified and extended. R. N. R. B.

THE STANDARDS AND FUNCTIONS OF MUSEUMS.

OUR forefathers regarded museums simply as storehouses for freakish, reminiscent, or merely curious objects, and as the place in which to deposit the various oddments presented by travellers abroad. There was no "purpose" in the display of the objects exhibited, other than that of perchance amusing stray visitors. So far as this country is concerned, the new era of museum management began with the foundation of the British Museum at Bloomsbury, when the first attempt was made to eliminate the purely "showman" element and substitute meaning and purpose in the arrangement of its contents. As compared with the Continental museums, it stands easily first in the character of its endeavours to interest, as well as instruct, the public. But in this we have serious rivals in the museums of the United States, as may be gathered from the forty-sixth annual report of the American Museum of Natural History. In this, and other similar institutions in America, huge sums are spent on large groups of mammals and birds mounted to reproduce the exact environment in which such animals lived. And this illusion is further heightened by skilfully painted backgrounds, executed by artists who accompany the collectors in order that they may reproduce the actual environment in which the specimens lived. This, however, is but an extension of the methods of exhibition introduced by the British Museum many years ago.

In exhibitions designed primarily to instruct rather than to amuse, it is an open question whether our rivals are not over-reaching their ideals—at any rate, in so far as the work of a natural history museum is concerned. Mineralogy, for example, no doubt must find a place here, but large models of a copper mine, such as that reproduced here, and the method of raising ore, would seem to have a more appropriate place in a museum of technology.

The students' collections of such museums must either be of insignificant proportions, or the staff must be much larger than that attached to museums in

Copper Queen Mine Model, Department of Geology and Invertebrate Palæontology. The American Museum of Natural History.

Great Britain, otherwise the curatorial work in connection therewith would make it impossible for the staff to devote so large a portion of their time to work which is done, indifferently well, it is true, in this country, under the auspices of the Board of Education, as "Nature-study." That this should be so is unfortunate, for, as a means of awakening the intelligence and powers of observation, there is no more efficient aid than the study of natural history, using this term in its widest sense.

In addition to lectures to children and teachers, special rooms are set apart in American museums for children's collections, while this work is supplemented by travelling museums sent round from school to school by means of motor-vans. Something of this kind could well be imitated in this country.

The department of public health in the American Museum of Natural History answers to no more than one aspect of the department of economic zoology of the British Museum of Natural History—that which concerns the organisms injurious to man—for no attempt seems to have been made to bring together a collection of domesticated animals. On the other hand, our rivals are ahead of us in having instituted

an exhibition of living bacteria such as more or less affect the well-being of the human race.

It is to be hoped that this report will be widely read in this country by all who are concerned with the management of museums, for it is full of most valuable information, and it is becoming increasingly clear that the museum is becoming more and more a factor in the well-being of the community. W. P. P.

FORTHCOMING BOOKS OF SCIENCE.

ANTHROPOLOGY AND ARCHÆOLOGY.

A. Brown and Son, Ltd.—Early Staffordshire Pottery, being an illustrated description, by C. Earle, of the Earle Collection, deposited in the Municipal Museum, Hull, with a preface by F. Falkner, and an introductory chapter on The Evolution of the Potter's Art, by T. Sheppard. *Cambridge University Press.*—The Northern Bantu: An Account of some Central African Tribes of the Uganda Protectorate, Rev. J. Roscoe (Cambridge Archæological and Ethnological Series). *Duckworth and Co.*—Where Animals Talk: Folk Tales of West Africa, Rev. R. H. Nassau. *Seeley, Service and Co., Ltd.*—Prehistoric Man and His Story, Prof. G. F. Scott Elliot, illustrated. *Macmillan and Co., Ltd.*—An Untamed Territory: The Northern Territory of Australia, Elsie R. Masson, illustrated; *The S.P.C.K.*—The Language Families of Africa, A. Werner; The Red Indians of Canada, Rev. J. Hines, illustrated. *Williams and Norgate.*—The Antiquity of Man, Prof. A. Keith, illustrated.

BIOLOGY.

F. Alcan (Paris).—L'Evolution des Plantes, N. Bernard. *John Bale, Ltd.*—Les Plantes Tropicales, P. de Sornay, translated; Rubber Industry of the Amazon, J. F. Woodroffe; Guide to Cocoanut Planting, R. W. Munro and L. C. Brown; Braun's Animal Parasites: brought up to date, mostly rewritten, with numerous additions and fresh illustrations, by Prof. Stephens and Dr. H. B. Fantham, edited by F. V. Theobald. *Cambridge University Press.*—Botany: A Text-Book for Senior Students, D. Thoday; Mimicry in Butterflies, Prof. R. C. Punnett. *Cassell and Co., Ltd.*—The Greenhouse: Its Flowers and Management, H. H. Thomas; Bulb Growing for Amateurs, H. H. Thomas. *Dulau and Co., Ltd.*—The Flowering Plants of Africa, F. Thonner, illustrated. *Duckworth and Co.*—Birds and Man, W. H. Hudson, new edition. *H. Holt and Co. (New York).*—Mechanism of Mendelian Heredity, T. H. Morgan and others. *Longmans and Co.*—British Birds, written and illustrated by A. Thorburn, vols. ii., iii., and iv. *Methuen and Co., Ltd.*—How to Know the Ferns, S. L. Bastin, illustrated; British Insects and How to Know Them, H. Bastin, illustrated. *L. Reeve and Co., Ltd.*—Transactions of the London Natural History Society for the Year 1914. *Whittaker and Co.*—Recent Researches in Plant Physiology, Dr. W. R. G. Atkins.

CHEMISTRY.

G. Bell and Sons, Ltd.—Quantitative Laws in Biological Chemistry, Dr. Svante Arrhenius. *C. Griffin and Co., Ltd.*—Text-Book of Inorganic Chemistry, edited by Dr. J. Newton Friend; The Alkali Metals and their Congeners (Group I. of the Periodic Table), Dr. A. J. Walker; The Alkaline Earth Metals and their Associates (Group II. of the Periodic Table), Dr. H. V. A. Briscoe and E. Sinkinson; Aluminium and its Congeners, including the Rare Earth Metals (Group III. of the Periodic Table), H. F. V. Little; Carbon and its Allies (Group IV. of the Periodic Table), Dr. R. M. Caven; Nitrogen and its Congeners (Group V. of the Periodic Table), Dr. J. C. Withers and H. F. V. Little; Sulphur and its Congeners (Group VI. of the Periodic Table), Dr. Douglas F. Twiss and A. V. Eldridge; The Halogens and their Allies (Group VII. of the Periodic Table), Dr. G. Martin and E. A. Dancaster; Iron and the Transitional Elements (Group VIII. of the Periodic Table), Dr. J. N. Friend and Dr. W. E. S. Turner; The Manufacture of Ink: The Production and Properties of Printing, Writing, and Copying Inks, C. A. Mitchell and T. C. Hepworth, new edition, illustrated. *Gurney and Jackson.*—The Manufacture of Sulphuric Acid and Alkali, vol. iv., containing Electrolytical Methods, Prof. G. Lunge; Coal Tar and Ammonia, Prof. Lunge and Dr. J. Kraemer, new edition. *Longmans and Co.*—Chemistry, First Stage, F. P. Armitage. *Methuen and Co., Ltd.*—A Senior Experimental Chemistry, Drs. A. E. Dunstan and F. B. Thole. *John Wiley and Sons, Inc. (New York).*—Quantitative Chemical Analysis, Prof. F. A. Gooch; The Microscopy of Vegetable Foods, Dr. A. L. THE BRITISH ASSOCIATION.

SECTION C.

GEOLOGY.

OPENING ADDRESS[1] BY PROF. GRENVILLE A. J. COLE, F.G.S., M.R.I.A., PRESIDENT OF THE SECTION.

THE geologist has long been accustomed to regard the crust beneath his feet as subject to changes which are immeasurably slow in comparison with the duration of his personal life. James Hutton has sometimes been charged with catastrophic tendencies, in requiring a complete wearing away of the continents, followed by a somewhat sudden restoration of the land-surface. But he was careful to urge[2] that "the powers of nature are not to be employed in order to destroy the very object of those powers; we are not to make nature act in violation to that order which we actually observe." He remarks[3] that "this world is thus destroyed in one part, but it is renewed in another; and the operations by which this world is thus constantly renewed are as evident to the scientific eye as are those in which it is necessarily destroyed." Yet the operations that are to "give birth to future continents," as well as those that wear down a continent to the level of the sea, are not the result of "any violent exertion of power, such as is required in order to produce a great event in little time; in nature, we find no deficiency in respect of time, nor any limitation with regard to power." Far from believing in the complete loss of the former land-surface before upheaval raised the new, Hutton points out that "the just view is this, that when the former land of the globe had been complete, so as to begin to waste and be impaired by the encroachment of the sea, the present land began to appear above the surface of the ocean. In this manner we suppose a due proportion to be always preserved of land and water upon the surface of the globe, for the purpose of a habitable world, such as this which we possess."

Changes in the Relative Proportions of Sea and Land.

Few geologists, however, will now urge with Hutton that a "due proportion" has always been preserved between land and water on the surface of the globe, if by those words is meant a proportion such as we now enjoy. If we go back to early times, we must consider, with R. A. Daly,[4] the possible grouping of the land against which the Huronian or late pre-Cambrian sediments were formed. Daly has imagined, as one of the causes contributing to a "limeless ocean," a primitive distribution of land and water very different from that which determines our continental land to-day. His pre-Huronian land-surface is pictured as merely a number of large islands, on which no long and conspicuous rivers could arise.

It may be said that this primitive condition of the distribution of land and water is very unlikely to return. But we have evidence that Hutton's "due proportion" has been interfered with from time to time. The very general spread of the sea over the land-margins in Cenomanian times is attributable to a shallowing of the ocean-floors, and it is difficult to say whether this process has been rhythmic or exceptional in the history of the globe. The Carboniferous period opened with marine conditions over a large part of the northern hemisphere, indicating, not only a continuation of the Devonian seas, but an overflowing of much of the Caledonian land. The same period closes with an extension of the continental edges, and the formation of swampy flats, in which the vegetation of the epoch has been abundantly preserved. Similarly, the sea which deposited the Cretaceous strata, after encroaching alike on South Africa and Scandinavia, withdrew to a considerable extent in Eocene times.

The Foundations of the Earth's Crust.

Hutton remains at present unassailable in one of his most remarkable propositions. For him, the oldest rocks that we know are sedimentary, and these sediments differed in no respect from those of modern days. This conclusion has perhaps not received the full attention it deserves. It now appears

[1] Abridged by the author.

[2] "Theory of the Earth" (1795), vol. ii., p. 547.

[3] *Ibid.*, p. 562.

[4] "The Limeless Ocean of Pre-Cambrian Time," *Amer. Journ. Sci.*, vol. xxiii. (1907), p. 113; and more fully in "First Calcareous Fossils," *Bull. Geol. Soc. America*, vol. xx. (1909), p. 157.

certain that we possess no record of a sedimentary type peculiar to the early stages in the formation of a habitable crust. If such a type existed, it has been lost to us through subsequent metamorphism, amounting to the actual fusion and redistribution of its constituents. The Grenville Series of North America rests on a floor of granitoid rock, which is intrusive in it, and which belongs to the oldest of various irruptive groups. The Grenville Series includes conglomerates, false-bedded quartzites, and a development of limestone that is altogether exceptional for pre-Cambrian times. In Finland,[5] sediments have been traced down to the layer where their original characters vanish in a general "migmatitic" ground. Conglomerates and phyllites occur among them, and near Tampere (Tammerfors) the seasonal stratification is as well recorded in a Bottnian shale as it is in the Pleistocene clays made famous in Sweden by De Geer. Vein-gneiss (Adergneis) underlies these ancient systems, and represents their destruction by the injection of granite from below. If we accept the hypothesis of Chamberlin, Hutton's position becomes strengthened by the postulation of an unfused planetesimal crust, and the restriction of molten masses and hydrothermal activity to the interior of a consolidating globe.

So far as we have any record left to us, Hutton remains fundamentally in the right. All modern research shows that the schists and gneisses can be explained by causes now in action. The vast majority of schists were at one time normal sediments; others were tuffs or lavas; but, whether originally sedimentary or igneous, they owe their present characters to widely spread regional metamorphism.

The Undermining and Weakening of the Foundations of the Crust.

Is there, then, any reason to depart from Hutton's position as to the recurring cycle of events in the history of continental land? I think it must be admitted that the isostatic balance was far more frequently disturbed in what we may call Lower pre-Cambrian times than it has been in more recent periods. Local fusion must be regarded as an important cause of crustal weakening. If we wish to study the nature of the process, it is reasonable to examine regions that have at one time lain deep within the crust. Such regions are provided by the broad surfaces of Archæan rocks that were worn down through continental decay before they sank beneath the Cambrian sea.

It is well recognised that an ancient continent at one time stretched across the northern hemisphere. Wherever later deposits have been stripped from its surface, from central Canada to the Urals, and probably far beyond, we find that the older materials of this undulating continental platform consist largely of intrusive igneous rocks. These, moreover, have frequently a gneissic structure. Again and again, strongly banded gneisses occur, in which granitic material, verging on aplite, alternates with sheets of hornblendic or biotitic schist. The biotitic varieties can often be traced back into amphibolites. In places, lumps of these amphibolites are seen, streaked out at their margins, and providing a clear explanation of the dark bands throughout the gneiss.[6]

[5] J. J. Sederholm, "Ueber eine archäische Sedimentformation im südwestlichen-Finland," *Bull Comm. géol. Finlande*, No. 6 (1899), p. 215.

[6] Since the historic works of A. C. Lawson (for example, "Report on Rainy Lake Region," *Geol. Surv. Canada*, Ann. Report for 1887, plates v. and vi.), these features have been traced in many areas. Compare W. H. Collins, "Country between Lake Nipigon and Clay Lake, Ontario," *Geol. Surv. Canada*, Publication 1050 (1909), p. 52; A. L. Hall, Presidential Address on the Bushveld Complex, *Proc Geol. Soc., S. Africa*. 1914, xxii; P. A. Wagner on Rhodesian gneisses, *Trans. ibid.*, vol. xvii., 39; and works cited in the next reference.

This swallowing up of a mantle of basic material by a very different and highly siliceous magma rising from below is, indeed, seen to be a world-wide feature, wherever we find the lower crust-layers brought up within reach of observation. The tuffs and lavas of the Keewatin series have supplied the dark material in Canada, and similar rocks have been worked up into the gneisses of Galway, Stockholm, and Helsinki. The frequency of amphibolite in these ancient composite rocks is explained by the fact that this type of rock is the final term of various metamorphic series. While many lumps, for instance, in the gneisses of Donegal are residues of Dalriadian dolerites (epidiorites), others, rich in garnet and green pyroxene, and often containing quartz, are derived from a mixture of sediments in which limestone has been prevalent.[7] During the absorption and disappearance of these masses in the invading granite magma, the amphibole acquires potassium and breaks down into biotite, and biotite-gneisses result, which may extend over hundreds of square miles.

The details of such an igneous invasion are worthy of careful study, since only in this way can we follow out the progress of subcrustal fusion. We see the highly metamorphosed material further attacked by the great cauldrons under it, and becoming seamed with intersecting veins. Block after block has been caught, as it were, in the act of foundering into the depths. In the gradual absorption of these blocks, and their penetration by insidious streaks of granite, we see pictured on a few square yards of surface the destruction of a continental floor.

The invasion of a "hard and brittle"[8] crust by an attacking magma was finely described by Lawson in 1888. Lawson pointed out that the Laurentian gneisses gave no evidence of having "yielded to pressures and earth-stresses." The folding of the overlying series was prior to the solidification of the gneisses, and occurred[9] "while the latter were yet in the form of probably a thick, viscid magma upon which floated the slowly shrinking and crumpling strata of the Coutchiching and Keewatin series. . . . Large portions of these rocks have very probably been absorbed by fusion with the magma, for the Laurentian rocks appear to have resulted from the fusion not simply of the floor upon which the Coutchiching and Keewatin rock first rested, whatever such floor may have been, but, also, with it, of portions of those series."

The conversion of the lowest Archæan series, the Coutchiching sediments, into crystalline schists is attributed to thermal metamorphism, and to hot vapours streaming from the molten floor. Lawson realised the importance of shattering in allowing a magma to advance into an overlying "brittle" series, and he is, so far as I know, the first observer to develop in satisfying detail what is now known as the stoping theory of igneous intrusion.

James Hutton always had in mind the effect of heat in "softening" lower layers of the crust. His consolidation of strata by heat is preceded by a stage of melting. Sederholm,[10] while referring back to Hutton as the pioneer, shows how in the vein-gneiss

stage the unmelted sediments exhibit plasticity and become intensely contorted. The softening, in fact, induces flow. There is here no crushing or mylonitisation, but rather a viscid running of constituents, some on the verge of fusion, some, I venture to think, actually fused. Such rapidly repeated and intricate folding is most intense when *lit par lit* injection has set in, and when the whole composite mass has become weak and plastic. The presence of confined water in aiding this plasticity must on no account be overlooked.

It may be well to illustrate this contention by one or two concrete instances from districts not remote from us at the present time. The noble cliffs of Minaun in Achill Island have been worn by the Atlantic from a mass of evenly-bedded quartzites of Dalriadian age. These are invaded by veins of a very coarse red granite, the main mass of which lies below the present sea-level.[11] The edges of the strata appear fairly horizontal on the cliff-face; but contortion sets in towards the base, and the hard resisting rock has here[12] "undergone intense crumpling and overfolding, such as one meets with on a large scale in mountain ranges, and this contorted flow seems entirely due to the yielding that has taken place in the region of heating." The large size of the constituent crystals of the granite indicates that the surrounding rock was still maintained at a high temperature.

South of Foxford, again, in the county of Mayo, the granite of Slieve Gamph invades a series of mica-schists and quartzites. The margin is cut, as usual, by veins that filled the cracks both of the main granite and the metamorphosed sediments. These sediments have become, prior to the shattering, crumpled and overfolded along the contact-region, and the section upon the glaciated slope resembles that of a fluidal rhyolite on a highly magnified scale.

The wonderful contortion of the composite mass that forms the north end of the Ox Mountains (Slieve Gamph) in the county of Leitrim gives a similar impression of viscid flow. The melting of a single constituent of the invaded schists, which here include amphibolites, would enable them to yield in response to the pressures that were forcing the granite magma in thin sheets between them. Their metamorphism is thermal, and the forces that have produced the crumplings are not those of shearing acting on a solid mass, but may have operated from a distance hydrostatically through the magma.

Again, where limestones occur near granite contacts amid a series of various sedimentary types, they display folded structures in an altogether exceptional degree. Silicates have developed along their bedding-planes, but these have become contorted and rolled upon one another as metamorphism reached its maximum stage. At Maam Cross and Oughterard, in the county of Galway, along the margin of the great granite mass that stretches thence southward to the sea, these flow-structures are conspicuous on weathered surfaces.

The main object of the foregoing discussion is to point out that the Huttonian cycle, in which thermal changes play so large a part, implies a serious weakening of the crust as magmas advance into it from below. The extensive metamorphism of the pre-Cambrian strata, which amounts to a distinctive feature, must, I think, be attributed, not to special intensity of tangential pressures in early times, but to frequency of igneous attack. Much of the crumpling of our schists may result from Hutton's "softening," the pressure being supplied from superincumbent masses, or even hydrostatically, and the flow occurring laterally, or vertically downwards, towards regions where destruction by absorption was going on. The features seen during the falling in of the walls of the lava-lake of Kilauea in Hawaii afford some idea of what takes place in zones of melting within the crust.

Under such conditions in early pre-Cambrian times, even the surface-rocks must have fallen in at some points and have been replaced by igneous extrusions. Isostatic adjustments must have been very frequently disturbed. Folding of rocks, as a phenomenon of lateral surge and flow, must have made itself freely felt at the earth's surface. It is safe to assert that such conditions have not been repeated on a broad scale at any geological period subsequent to the spread of the Olenellus-fauna. Geochemical evolution, however, may have surprises still in store, and, in spite of long tradition, we are disinclined nowadays to rely too strongly on arguments based upon the sanctity of human life.

Possible Breaks in the Slow Continuity of Earth-movement.

1. *The Mountain-building Stage.*

Even with the thickened sedimentary crust beneath us, and the confidence inspired by our limited experience of the earth, we may ask if subterranean changes may not still result in catastrophes at the surface.

What, in fact, is likely to occur if a mountain-building episode again sets in? Such episodes, affecting very wide areas, have undoubtedly recurred in the earth's history. We do not know if they are rhythmic; we do not know if they represent a pulsation, decreasing in intensity, inherited from the stars and hampered by increasing friction; we do not know if they record internal chemical changes, which have no climax, because they are neither cyclic nor involutionary, but evolutionary. The mid-Huronian chains, now worn down and supplying such valuable horizontal sections, were evidently of great extent; but we cannot say that they were vaster than those of later times.

The phenomena accompanying the growth of a single chain in the Cainozoic era give us, at any rate, ample food for thought. Though the narrow cross-section of the core of such a chain limits our field of observation, the same inpressings of igneous material, and the same features of rock-weakening and rock-destruction, may be observed as in the immense basal sections exposed in the Archæan platforms. The progress of geological time has not diminished the activity in the depths. The granodiorite of western Montana,[13] for instance, which intruded during an uplift in early Eocene times, has attacked the Algonkian sediments of the district, producing phenomena of stoping and assimilation in the true "Laurentian" style.

In the western and central Alps, again, the absence of any fossiliferous strata older than the Carboniferous arouses some surprise, until we find that many of the granitic intrusions are of late Carboniferous age. The crystalline schists west of Časlav in Bohemia and in the Eisengebirge are now attributed by Hinterlechner and von John[14] to the metamorphism of Ordovician strata by younger granite, which intruded in post-Devonian and probably in Carboniferous times. Much of the gneiss and granite of the Black Forest and the Vosges is now, moreover, removed from the Archæan, and is shown to be associated with the Armorican movements.[15] These vast intrusive

masses occupy the place of strata of pre-Permian age. The great development of thermal metamorphism in the Erzgebirge and in Saxony,[16] two classic regions of the dynamometamorphic school, is now widely recognised, and this activity is also assigned to late Carboniferous times. The work of C. Barrois in Brittany is concerned with absorption-phenomena resulting from intrusions during the same mountain-building epoch.

Sederholm[17] has suggested that the ground above an area affected by processes of mountain-building cracks and becomes faulted, while the more plastic zone below flows under pressure into folds. But the blocks of the "brittle" layer, as Lawson has it, may be seriously displaced by movements in the zone of folding, and subsidences of a regional character may occur. The pressure that has driven an excess of matter to the region of overfolding has squeezed it from beneath an adjacent region. Crumpling and overfolding are accompanied by a shearing away of the matter in one zone from that of another which overlies it; this must result in considerable disturbance of the zone nearer the surface.

We usually regard such disturbances from the uniformitarian point of view. May not, however, actual mountain-building be the break in a slow process of "softening," to use Hutton's term? For a long time the isostatic balance suffers only small disturbances, restoring itself automatically on a gently yielding underworld. Then something gives way; something—a large mass of supporting rock—suffers a change of state. The balance is destroyed abruptly, and mountain-building and rapid subsidences have their day. O. Ampferer,[18] with his customary largeness of view, has referred superficial evidences of disturbance, such as mountain-ranges, to dragging movements of a mobile *Untergrund*. He urges that physical and chemical changes within the earth may produce considerable local changes of volume. Vertical movements lead to upfolding, and this leads to gravitational sliding. The zone of folding that we have been considering as normal near the *Untergrund* thus becomes transferred to the surface of the earth.

I am not now concerned with the causes of folding, beyond the fact that at a certain critical stage the material involved may move at a rapid rate. Changes of state, physical and chemical, occur with some abruptness. In the case of rocks, the softening or melting of even one constituent may allow of flow, and, as we have observed, this flow in a lower layer may soon become manifested in surface-changes.

Ampferer and Hammer[19] have recently considered the overfolded structure of mountains as due to a considerable local reduction in volume of the *Untergrund*. The upper crust presses inwards from opposite sides, and the parts that are thrust downwards become absorbed and carried away with the retreating region of the *Untergrund*. The surviving parts fall over on either side, producing, as the whole continues to close in, folds that are not so very different from the now familiar ***nappes de recouvrement*** which these authors hesitate to accept. The important point for our present purpose is the restatement of the results of gravitation on the flanks of an uprising chain.

The surprising thing about our folded mountain-chains is the way in which they have been eroded parallel to the strike of the overthrust sheets or overfolds. Apart from occasional detached "klips," the distal parts of these masses must have been at one time continuous with those proximal to the root-region. The forward movement could not have occurred if denudation had negatived the effects of folding on the surface.

The marine or lacustrine deposits of the age immediately preceding that of uplift obviously cannot be consolidated at the epoch of upheaval. Gotlandian sands and muds must have overlain the heaving masses that rose as Caledonian land. The swamps of the Coal Measures were contorted in the Armorican chains: the highest beds of these must have been as yielding and as capable of flow as the Flysch that overlay the growing Alps. In all these cases, familiar to us in Europe, the covering masses must have responded to the crumpling under them, and, when reared to dangerous eminences, rapidly became a prey to denudation and gravitational downsliding. They can scarcely be regarded as protective, and their removal would leave the brittle masses below more liable to fracture and to the "calving" process that forms klips.

In some cases separation seems to have taken place as the moving mass fell forward. The klips of hard material embedded in softer strata are thus a kind of rock-spray, hurled in advance of the breaking earth-wave.

Termier[20] in no wise fears to speak of the progress of a "traîneur écraseur" during mountain-building as "soudain et rapide comme une rupture d'equilibre, le dernier acte, longuement pépar*é*, mais joué d'*emportement*, de ce drame grandiose."

Rupture combined with rapid movement of the rocks need not be the last act of the drama; but, the more we examine the history of folded chains, the more probable it appears as a culminating episode. The original cover of our present ranges has been lost by denudation. Earth-sculpture in these regions of high altitude and vehement attack has removed much of the evidence that we seek. What remains, however, may lead us to feel that no part of the world in historic times has experienced a mountain-building episode.

Such relatively catastrophic stages have, indeed, not been common in the long history of the earth since pre-Cambrian times. It appears that now and again the "orogenic collapse" of some considerable area disturbs the balance in the crust and spreads far through the upper layers like a disease. Or it may be that the thermal cause of the collapse is common to the whole earth at the same time, and becomes manifest in responsive regions far apart. In any case, the weak places give way and the more resisting ones close in. A readjustment is effected, which then endures through long geological time.

The imminent menace of crustal changes was brought home to us during the terrible period from April 4, 1905, to January 14, 1907, the final twelve months being marked by a veritable earth-storm. Geologically speaking, however, we are near enough to the Tortonian epoch to look forward with some confidence to a quiescent phase. But some day, in its due season, the earth will once more be active. When that time comes, no ingenuity of man will suffice to meet it. Earthquake after earthquake, increasing in intensity, will probably have driven the population to a distance from the threatened zone. Concentration of the folding along a particular earth-line will limit the region of absolute destruction; but the undulations spreading from it, in response to the heavings of the chain, will offer sufficient chances of catastrophe. In the case of our youngest mountain-ranges, these undulations remain perpetuated as domes

and dimplings of the crust, which are already worn down or infilled respectively by denudation and deposition. Their present forms and places record the last movements of the earth-storm, just as a buckled tramway-rail records the passage of an earthquake. How shall we gauge to-day the intensity of their rise and fall?

In the case of the city devastated by an earthquake, the débris is cleared away, and our descendants in time discover the distorted rails beneath the healing mantle of new grass. Will they realise from this alone the preliminary tremors, the sudden arrival of the culminating vibration, the shock that overcame the elasticity of the crust beneath them, and then the gradual establishment of the conditions under which they have passed their peaceful lives? The crumpled wreckage lies there in evidence before them; but how will they distinguish the work of a few stormy seconds from that due to the gentle earth-creep of a century?

(2) *Regions of Subsidence.*

It was probably E. Suess who brought home to most of us the importance of regions of subsidence in defining the lowlands and the sea-basins from the upstanding masses of the crust. While one region may be folded, another may be broken into blocks; and the two types of movement, that due to tangential thrusting and that due to vertical uplift and down-faulting, may appear in the same region and may alike play their part in producing a lowering of large areas. The domes and dimples that occur beyond the region of acute crumpling may be intensified into fault-blocks by fracture of their boundaries. If catastrophes are possible during uplift, we may look for them also during subsidence.

The cutting-up of mountain-chains by transverse fractures has resulted in the loss of huge blocks beneath the sea. In such cases it is clear that faulting has run a long way ahead of denudation. All trough-valleys, which are often called, somewhat misleadingly, rift-valleys, raise the same questions as to the nature of the steps by which they have been produced. The Rhine Vale, one of the most closely studied examples, dropped 8000 ft. within the limits of Oligocene time. It is improbable that the numerous faults now traceable operated with concerted gentleness.

Abruptness of certain Geographical Changes.—River-capture.

There is a totally different class of terrestrial phenomena which lends itself also to speculation, or to that imaginative faculty, proper to our Section, which enables the geologist to reconstruct. Geographers have taught us to speak lightly of river-diversion and river-capture, and to treat them as frequent occurrences in the history of existing lands. It is interesting to inquire what this process on a large scale may involve.

The draining of the Ragunda lake in Sweden [21] in 1796, by the rapid cutting of a ravine 100 ft. deep in a soft barrier, shows how many of our Glacial lakes, dammed by morainic matter, may have excavated their outlet gorges and run dry in the course of a few hours. The history of the temporary lake behind the Gohna landslip, so brilliantly studied by our vice-president, Sir Thomas Holland,[22] provided a lesson both in hill-destruction and catastrophic flooding. The diversion of the Colorado River, however, in 1905, into the sluice leading to the Salton Sink gives us a definite illustration of river-capture. The "New River" thus produced in the depression to the north-west of Calexico cut a valley 70 ft. deep through the agricultural land that it was meant to serve, and worked the head of this valley backward at the rate of a third of a mile a day.

One of the most remarkable instances of river-diversion in the European record is that of the waters from the north side of the central Alps. At the close of the Pliocene period, the north slopes of the St. Gothard mass and the Bernese Alps, supplying the torrents of the Reuss-Aar-Saane system, drained across the hummocky land near Bâle and sent their waters over to the Doubs. The great Rhine-trough drained southward, and its streams formed tributaries of the Alpine flow near Bâle. The Mainz basin, however, which was infilled by Lower Pliocene alluvium, became tapped by the head of a river that had long run northward from the Hunsrück-Taunus range. This river is the Rhine that we know north of Coblenz, and its alluvium was then spread out where the sea now stretches between Holland and the Yorkshire coast. Its mature valley is still traceable [23] above the present stream-cut in the hills. This river could have no direct influence on the course of the drainage from the Alps. But the bulging of the land at the north end of the Juras still continued. As the text-books remark with some complacency, the Burgundian gate was closed, and the river that had previously crossed westward was diverted northward to the Rhine-trough.

Can we exactly picture what this means? The whole Reuss-Aar-Saane system "on some particular day began to flow northward along the far older tectonic trough, carving away the infilling of detritus, washing back tree-stems that were floating quietly from the Lake of Mainz on their way to the Mediterranean, and finding, when it reached that lake, a notch sufficiently low for its escape across the Hunsrück-Taunus range. An enormous body of water was thus added to that which had formed in Pliocene times a mature valley across these hills." [24] The system indicated above, representing the flow from a hundred miles of snow-clad mountains, must have made a remarkable change in the stream across the Armorican hills. When the Alpine water arrived at the Mainz basin, and found its way into the notch formed by the Pliocene Rhine, it poured down upon the forest-covered delta-land. The changes that have occurred in the unconsolidated ground of Holland in historic times furnish some picture of what must have happened in the prehistoric delta of the Rhine. Land was suddenly built up at some points, islands were carved out at others, and the effects of the catastrophe must have been still manifest when the Scandinavian ice-sheet began to invade the mud-flats from the north.

The capture of a large river may be illustrated by the story of the Vistula. This noble stream represents in a remarkable way the drainage of 190 miles of the Carpathians. All this water becomes concentrated, at the apex of a reversed river-fan, at the east end of the Kielce hills, and it is probable that the upper Vistula was driven to join the San by the advancing ice-front of the Riss age, and that both rivers then escaped southwards. The joint waters were again held up when the Fennoscandian ice rested along the line marked by the Baltic Heights, and it is well known that a great river flowed westward along the stagnating ice-front where now the marshes of the Netze mark its course. As the ice-front shrank backward, towards the Baltic basin,[25] streams flowed down

[25] R. Lepsius (*Geologie von Deutschland*, pt. 2, p. 511) urges that the sinking of the floor of northern Europe led to this northward trend of the streams.

over the sands and boulder-clays and cut their valley-heads back southward. Overflows may have taken place on the unconsolidated wall of the great east-and-west river, which was now deprived of its barrier of moraine-filled ice. In one way or another, the shallow valley of the main river was tapped near Kustrin, and the Oder, rising in the Moravian plateau, was sent northward as an independent stream. Similarly, the Vistula was carried off at Fordon, where the bend due to capture is conspicuous at the present day; and the whole drainage of the north wall of the Carpathians swept across the drift deposits down the course of some hitherto unimportant stream. Along the valley thus carved out, brown and yellow cliffs now rise above the marshy flood-plain, and the red castles of advancing Germany have for centuries looked down firmly on the stream. It is quite contrary to our customary philosophy, but a good corrective all the same, to ask ourselves if this lower valley of the Vistula, eighty miles in length, was shaped in a few months or a few years. The main part of the excavation, across unconsolidated lands, may have occupied less time than the building of the strongholds at the fords.

Conclusion.

In spite of the swamping of the Alkmaar country in 1825, in spite of the tragedy of Messina only seven short years ago, we feel that Europe is a settled continent, and we judge the past and future by the present superficial peace. We have applied the same thoughts to human movements, and the inconceivable has happened in our midst. We naturally find it difficult to carry our minds back to epochs when the earth-blocks may have parted asunder as ice parts across the polar seas. We have still, however, very much to learn about causes now in action; and the mystery of the earth, and of our connection with it, grows upon us as we learn. Can we at all realise the greatest change that ever came upon the globe, the moment when living matter appeared upon its surface, perhaps over a few square miles? Matter is either dead or living, that is, endowed with life; there is no intermediate state. And here was living matter, a product of the slime, if you will, but of a slime more glorious than the stars. Was this thing, life, a surface-concentration, a specialisation, of something that had previously permeated all matter, but had remained powerless because it was infinitely diffuse? Here you will perceive that the mere geologist is very much beyond his depth. Let us return to our orderly studies, our patient hammerings, our rock-slices, our chiselling out of fossil shells. Behind it all is the earth itself, quiescent, it may be, but by no means in the sleep of death. As Termier puts it, "La planète n'est pas encore morte; elle ne fait que dormir." If in this address I have dwelt upon the possibility of rapid changes in its surface, no member of our association will feel the least alarm.

Felix qui potuit rerum cognoscere causas,
Atque metus omnes, et inexorabile fatum
Subiecit pedibus, strepitumque Acherontis auari.

SECTION E.

GEOGRAPHY.

OPENING ADDRESS[1] BY MAJOR H. G. LYONS, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

The Importance of Geographical Research.

THIS year, when the British Association is holding its meeting in times of the utmost gravity, the changed conditions which have been brought about by this war must occupy the attention of all the sections to a greater or less extent, and our attention is being called to many fields in which our activities have been less marked or more restricted than they might have been, and where more serious study is to be desired. The same introspection may be usefully exercised in geography, for although that branch of knowledge has undoubtedly advanced in a remarkable degree during the last few decades, we have certainly allowed some parts of the subject to receive inadequate attention as compared with others, and the necessity for more serious study of many of its problems is abundantly evident.

In order that we may see what advance has been made in the scientific study of geography in this country during the last quarter of a century, we must turn to the results that have been attained by the activity of geographical investigators who have devoted themselves to the serious study of various phenomena, and the detailed investigation of particular regions. If we do so I think we must admit that the number of original investigators in scientific geography who are extending its scope in this way is not so large as it might be, nor are we yet utilising sufficiently all the material which is available to us. Anyone who will examine the geographical material which has been published in any period which he may select for review will find that purely descriptive treatment still far outweighs the analytical treatment which alone can lead to definite advances in scientific geography. If pleasing descriptions of this or that locality are sought for, they are for the most part to be found readily in the very large amount of such material that has been and is being published each year by residents, travellers, and explorers; but if information is desired in the prosecution of a piece of geographical research, we are checked by the lack of precise details. Few descriptions of this class are sufficiently definite to enable the necessary comparisons to be made between one locality and others which are similarly situated; thoroughly quantitative treatment is for the most part lacking, and while a pleasing picture is drawn which is probably true in character, it is usually inadequately furnished with those definite facts which the geographer requires.

The opportunity to undertake long journeys through distant lands comes to few of us, but this is not the only direction in which research can be profitably undertaken, for there is no part of these islands where a geographer cannot find within his reach some geographical problem which is well worth working out, and which, if well and thoroughly done, will be a valuable contribution to his science. Even for such as cannot undertake such field work the library will provide a host of subjects which have not received nearly the amount of attention and of careful study that they deserve. The one thing essential is that the study should be as thorough as possible, so that all the contributory lines of evidence shall be brought together and compared, and so that the result may prove to be a real addition to geographical science on which other workers may in their turn build.

The ease with which a tract of country or a route can be described by the traveller, and the attractiveness of such a description of a little-known region, results in the provision of a vast quantity of geographical information, the greater part of which has probably been collected by those who have no adequate training in the subject. But anyone who has had occasion to make use of such material in a serious investigation is only too well aware how little precise and definite information he will be able to extract from the greater part of this wealth of material, and in most cases this is due to the traveller's lack of geographical knowledge. He probably does not know the pheno-

[1] Slightly abridged by the author.

mena which should be observed in the type of region which he is traversing, nor can he read the geographical evidence which lies patent to a trained observer at every point of the journey; much, therefore, of what he records may be of interest, but probably lacks data which are essential to the geographer if he is to understand the geographical character of the region, and utilise it properly.

Thus it happens that although the amount of geographical material which is being garnered may be large, the proportion of it which is available for use in a scientific investigation of an area is smaller than is probably realised by those who have not made the experiment. And yet it is only by this scientific investigation of selected localities or of a single phenomenon and by working them out as thoroughly as possible that any real advance in geographical science can be made. There should now be an ever-increasing number of geographers trained to proceed in their investigations by the true scientific method, and there should be a very considerable amount of sound work in various branches of the subject which aims at thoroughly investigating some phenomenon, or group of phenomena, so as to present a grouping of data, carefully verified and critically discussed, in order to arrive at conclusions which may form a useful addition, however small, to the sum of our geographical knowledge.

So far as I am able to judge, the output of serious work of this character is not nearly as large as it should be, and I would indicate some fields in which there is a lack of individual work of this character. Until more of it is undertaken we shall lack in this country the material from which the foundations of scientific geography can be built up, and while our own islands and the various parts of the British Empire furnish unrivalled opportunities for such work, there are still far too many subjects where the most thorough investigations have been made in other countries.

Mathematical geography presents a field for research which has had comparatively little attention paid to it in this country. In many respects this part of the subject is peculiarly suitable for such treatment, since it admits of the employment of precise methods to an extent which is not always practicable in cases where so many of the factors can only be approximately defined. The determination of positions on the earth's surface is carried to great refinement in the national surveys of most civilised countries in order to furnish the necessary controls for the preparation of large-scale maps, but when we pass to the location of travellers' routes, where considerable allowance has to be made for the conditions under which the observations have to be taken, we find that very inadequate attention is usually paid to the discussion of the results. Usually a mean value for each latitude, longitude, or azimuth is obtained by the computer, and he remains satisfied with this, so that when the route of another traveller follows the same line or crosses it at one or more points, it is almost impossible for the cartographer to say which of the two determinations of any position is entitled to the greater confidence. In this class of work, whether the results are obtained from absolute observations at certain points or from the direction of march, and the distance traversed, it is quite practicable to determine the range of uncertainty within which the positions of different points are laid down, and it is eminently desirable that this should always be done in order that the results of various routes which may intersect in partially known regions may be adjusted in accordance with definite mathematical processes. Some important expeditions on which infinite labour and considerable sums have been expended have presented their results, in so far as they relate to the routes which have been followed and the position of points which have been determined, in such a way that it is impossible to say with what precision such positions have been determined, and consequently any combination of these results with those of later expeditions has to be carried out empirically, since adequate data are no longer available for the employment of better and more scientific methods.

This crude and unsatisfactory way of treating observations, which in many cases have been obtained under conditions of the greatest difficulty and even hardship, is largely due to the lack of interest which geographers have shown in this part of their subject. Methods of observation and methods of computation are rarely discussed before any of our geographical societies or in any of our publications, and it is only by such discussions that the importance of properly working out the available material at a time when the observer can be consulted on points which are doubtful, or where further explanation is desirable, becomes generally appreciated.

No set of physical or astronomical observations is ever discussed or even presented without the degree of precision or trustworthiness being definitely stated; yet in geography this sound rule is too often neglected.

There are several regions where travellers' routes intersect which should provide ample material for the careful reduction and adjustment of the results. I fear, however, that there would be great difficulty in obtaining the original observations which are indispensable in such an investigation, and in the interest of research it is highly desirable that the original documents of all work of importance should be preserved and the place where they may be consulted should be recorded in the published account.

There is room in the geographical investigation of sea and land, even within the limits of the British Empire, for the employment of methods of observation and computation of the highest precision as well as of the simpler and more approximate kinds, but everyone who presents the results of his work should deem it his first duty to state explicitly the methods which he employed, and the accuracy to which he attained, in such a form that all who make use of them can judge for themselves of the degree of their trustworthiness.

In such work, while the instruments used are of great importance, too often the briefest description, such as "a 4-in. theodolite," is deemed sufficient. If the observer wishes his work to be treated seriously as a definite contribution to science we require to know more than this, and a clear account of the essentials of the instrument, a statement of its errors, and of the methods of observation adopted are the least that will suffice. The account of any expedition should treat so fully of the instruments, observations, and computations utilised to determine the positions of places visited that anyone can re-examine the evidence and form his opinion on the value of the results obtained. A mere tabular statement of accepted values, which frequently is all that is provided, is of small value from a scientific point of view. Probably one reason for this state of things is that too little attention is being paid by geographers to their instruments. Theodolites, levels, compasses, clinometers, tacheometers, plane-tables, pantographs, co-ordinatographs, planimeters, and the many other instruments which are used by the surveyor, the cartographer, the computer, have in no case arrived at a final state of perfection, but it is seldom that we find a critical description of an instrument in our journals.

Descriptions there are from time to time, but these are for the most part weak and insufficient. Not only is a technical description required, which treats fully of both the optical and mechanical details, but we need an extended series of observations with the instrument which have been made under the ordinary conditions of practical work, and these must be mathematically analysed, and the degree of the trustworthiness of the results clearly demonstrated. The description should be equally thorough and complete, including scale drawings showing the construction of the instrument as well as photographs of it. Nothing less than this is of any use to the scientific cartographer.

In this country the early advances of British instrument-makers of surveying instruments are far from being adequately represented in our national museum in a manner commensurate with their importance. The keen and enlightened zeal of geographers who are interested in this branch of the subject would doubtless quickly bring to light much still remaining that is of great interest, but which is yet unrecognised, while a closer attention to instrumental equipment would lead to improvements and advances in the types that are now employed. There is no modern work in this country on the development of such instruments, and references to their history are conspicuously rare in our journals, so that there is here an opportunity for those whose duties prevent them from undertaking travel or exploration of a more ambitious kind. In the same way, those whose opportunities of field work are few can find a promising field of study in the early methods and practice of surveying which have been discussed by many authors from classical times onwards, and for which a considerable amount of material exists.

In geodesy and surveying of high precision there is ample scope for all who are attracted by the mathematical aspect of the subject; the critical discussion of the instruments and methods employed and results obtained, both in this country and in other lands, provides opportunity for much work of real value, while its bearing upon geology, seismology, etc., has not yet been adequately treated here. The detailed history of this part of our subject is to be found in papers which have been published in the technical and scientific journals of other countries for the most part; here too little attention has been given to the subject, in spite of the large amount of geodetic work which has been executed in the British Empire, and which remains to be done in our Colonies and overseas Dominions.

The final expression of the surveyor's detailed measurements is found in the map, and the adequate representation of any land surface on a map-sheet is both a science and an art. Here we require additional work on all sides, for there is scarcely any branch of geography which offers so remunerative a field for activity as cartography. We need the cooperation of trained geographers to study requirements, and to make acquaintance with the limits of technical methods of reproduction, so that they may be in a position to deal with many questions which arise in the preparation of a map regarding the most suitable mode of presentation of data, a matter which is purely geographical, but which at the present time is too often left to the skilled draughtsman. Neither the compilation nor the reduction of maps is a merely mechanical process. The first requires great skill and care as well as technical knowledge and a sound method of treatment if the various pieces of work, which are brought together to make up the map of any considerable area, are to be utilised according to their true worth. This demands a competent knowledge of the work which has been previously done on the region, a first-hand acquaintance with the data collected by the earlier workers, and the critical examination of them in order that due weight may be given to the better material in the final result. This is not a task to be handed over to the draughtsman, who will mechanically incorporate the material as though it were all of equal accuracy, or will adjust discrepancies arbitrarily and not on any definite plan. Such preliminary preparation of cartographical material is a scientific operation which should be carried out by scientific methods and should be completed before the work reaches the draughtsman, who will then have but to introduce detail into a network of controls which has been prepared for him and of which the accuracy at all points has been definitely ascertained. Similarly in the second case the elimination of detail which must of necessity be omitted is an operation needing the greatest skill, a full understanding of the material available, and an adequate appreciation of the result which is being aimed at, such as is only to be found in a competent geographer who has made himself intimately acquainted with all the material which is available and has his critical faculty fully developed.

All these problems are well within the reach of the geographer to whom the opportunity of travel in other regions does not come, and in them he will find ready to his hand a field of research which is well worth working and which will amply repay any labour that is spent upon it. The same precise methods of investigation which are employed in the discussion of observations should be applied to all cartographic material in order to ascertain the exact standard of its trustworthiness, in which is included not only the correctness of distance and direction, but also the accuracy of the information which has been incorporated in it; and these may be brought to bear also on those early maps of which so many are preserved in our libraries in this country. In this field of study several investigators have already achieved results of great interest and value, but I think they will be ready to admit that there is here a wide and profitable field of activity for many more workers who will study closely these early maps and, not being contented with verbal descriptions, will use quantitative methods wherever these are possible.

In the study of map projections some activity has been visible in recent years, and we may hope that those who have worked in this branch of the subject will see that British geography is provided with a comprehensive manual of this subject which will be worthy of the vast importance of cartography to the Empire. The selection of suitable projections is receiving much more attention than was formerly accorded to it, but the numbers of communications on this subject which reach geographical journals are few and far between. The subject is not one which can appeal strongly to the amateur geographer, but its importance renders it imperative that the scientific geographer who realises its intimate bearing upon all his work should so arrange that the matter does not fall into the background on this account.

But it may be suggested that the lack of activity in mathematical geography is due to the somewhat specialised nature of the subject, and to the fact that the number of those who have received an adequate mathematical training and are prepared to devote themselves to geography is few. When we turn to physical geography in its treatment of the land we do find a field which has been more actively worked, for this is just the one to which the traveller's and explorer's observations should contribute most largely, and where therefore their material should be utilised

with the best results. Even here there is room for much more work of the detailed and critical type, which is not merely general and descriptive, but starts from the careful collection of data, proceeds to the critical discussion of them, and continues by a comparison of the results with those obtained in similar observations in other regions.

To take a single branch of physical geography, the study of rivers, the amount of accurate material which has been adequately discussed is small. In our own country the rainfall of various river basins is well known through the efforts of a meteorological association, but the proportion of it which is removed by evaporation, and of that which passes into the soil, has only been very partially studied. Passing to the run-off, which is more easy to determine satisfactorily, the carefully measured discharges of streams and rivers are not nearly so numerous as they should be if the hydrography of the rivers is to be adequately discussed; for although the more important rivers have been gauged by the authorities responsible for them in many cases, the results have usually been filed, and the information which has been published is usually a final value, but without either the original data from which it has been deduced, or a full account given of the methods of measurement which have been employed. For the requirements of the authority concerned such a record is no doubt adequate, but the geographer requires the more detailed information if he is to co-ordinate satisfactorily the volume discharged with local rainfall, with changes in the rates of erosion or deposition, and the many other phenomena which make up the life-history of a river. Here, too, it is usually only the main stream which has been investigated; the tributaries still await a similar and even fuller study.

In the same way we still know too little of the amounts of the dissolved and suspended matter which is carried down by our streams at various seasons of the year and in the different parts of their course.

In this one branch of the subject there is ample scope for workers of all interests in the measurement of discharges, in the determination of level, and of the movement of flood waves, in determining the amount of matter transported both in suspension and in solution, in tracing out the changes of the river channel, in following out the variation of the water-table which feeds the stream, in ascertaining the loss of water by seepage in various parts of its course, and generally in studying the hundred other phenomena which are well worth investigating, and which give ample scope for workers of all kinds and of all opportunities. There is work not only in the field, but also in the laboratory and in the library which needs doing, for the full account of even a single stream can only be prepared when data of all classes have been collected and discussed.

On the Scottish lakes much valuable scientific work has been done, and also on some of the English lakes, so that excellent examples of how such work should be done are available as a guide to anyone who will devote his spare time for a year or two in making a thorough acquaintance with the characteristics and phenomena of any lake to which he has access.

Coast-lines provide another class of geographical control which repays detailed study, and presents numberless opportunities for systematic investigation and material for many profitable studies in geography. The shores of these islands include almost every variety of type, and furnish exceptional opportunities for research of a profitable character, especially as lying on the border-line between the domain of the oceanographer on one hand and the physiographer on the other. The precise methods of representation which are possible on the land have to give way to a more generalised treatment over the sea, and the shore line is liable to be handed over to the latter sphere, so that there is much interesting and useful work open to anyone who will make an accurate and detailed study of a selected piece of coast-line, co-ordinating it with the phenomena of the land and sea respectively.

The teaching of Prof. Davis in pressing for the employment of systematic methods in describing the landscapes with which the geographer has to deal has brought about a more rational treatment, in which due recognition is given to the structure of the area, and the processes which have moulded it, so that land forms are now for the most part described more or less adequately in terms which are familiar to all geographers and which convey definite associated ideas, in the light of which the particular description is adequately appreciated. It has been urged by some that such technical terms are unnecessary and serve to render the writings in which they occur intelligible only to the few; that anyone should be able to express his meaning in words and sentences which will convey his meaning to all. There is no great difficulty in doing this, but in such descriptions to convey all that a technically-worded account can give to those who understand its terms would be long and involved on account of the numerous related facts which would be included. It is consequently essential in all accurate work that certain terms should have very definite and restricted meanings, and such technical terms, when suitably chosen, are not only convenient in that they avoid circumlocution, but when used in the accepted sense at once suggest to the mind a whole series of related and dependent conditions which are always associated with it.

The crystallisation of such geographical terms into true technical terms is an important step in the furtherance of scientific geography, but it must be done by the geographers themselves, and no means of doing this is more fruitful than the work of original research and investigation in definite areas or on specific problems.

If we now consider some of the problems of human geography we shall find the need for such systematic study to be even greater; for the variable factors involved are more numerous than in physical geography, and many of them are difficult to reduce to precise statement; the quantitative study of the subject is therefore much more difficult than the qualitative or descriptive, so that the latter is too frequently adopted to the exclusion of the former. The remedy lies, I believe, in individual research into special cases and special areas where the factors involved are not too numerous, where some of them at least can be defined with some accuracy, and where, consequently, deductions can be drawn with some precision and with an accuracy which gives grounds for confidence in the result. The settlements of man, his occupations, his movements in their geographical relations are manifested everywhere, and subjects of study are to be found without difficulty, but their investigation must be based on actual observation, and on data which have been carefully collected and critically examined, so that the subject may be treated as completely as possible, and in such a way that the evidence is laid before the reader in order that he may form his own conclusions.

It is probable that some of the lack of precision which is to be found in this part of the subject is to be attributed to the want of precision in its terminology. For many things in human geography good technical terms are required, but these must be selected by those who have studied the type of phenomenon concerned and have a clear idea of the particular conditions which they desire to associate with the term;

this is not the work of a committee of selection, but must grow out of the needs of the individual workers.

There is, it must be admitted, no small difficulty in using the same preciseness of method in this portion of the subject as is readily attainable in mathematical geography, and is usually practicable in physiography; but at any rate it is undesirable to indicate any condition as the controlling one until all other possible influences have been carefully examined, and have been shown to have less weight than that one which has been selected.

Whether the investigation deals with the settlements of man or his movements and means of communication, it is important that in the first instance problems of a manageable size should be undertaken and thoroughly treated, leaving larger areas and wider generalisations until a sufficient stock of thoroughly trustworthy material which is in the form in which it can properly be used for wider aims is available.

The relation of geographical conditions to small settlements can be satisfactorily worked out if sufficient trouble is taken and all possible sources of information, both of present date and of periods which have passed away, are utilised. Such studies are of a real value and pave the way to more elaborate studies, but we need more serious study of these simpler cases both to set our facts in order and to provide a methodical classification of the conditions which prevail in this part of the subject. Out of such studies there will grow such a series of terms with well-defined associations as will give a real precision to the subject which it seems at the present time to lack.

The same benefit is to be anticipated from detailed work in relation to man's communications and the interchange of commodities in all their varied relations. Generalised and descriptive accounts are readily to be found, and these are for the most part supported by tables of statistics, all of which have their value and present truths of great importance in geography, but the spirit of active research which aims at clearing up thoroughly a small portion of the wide field of geographical activities has unequalled opportunities in the somewhat shadowy relations between the phenomena which we meet in this part of the subject, for focusing the facts better, and obtaining a more exact view of the questions involved.

Where the geography of States (political geography) is concerned the same need for original investigation as a basis for generalisations may be seen. At the present time there is much said about the various boundaries of States, and in general terms the advantages and disadvantages of different boundaries under varied conditions can be stated with fair approximation to accuracy. But I do not know of many detailed examinations of these boundaries or portions of them where full information of all the factors involved can be found set out in an orderly and authoritative manner, thus forming a sure foundation for the generalised description and providing the means of verifying its correctness or revising it where necessary.

Perhaps there is really more scientific research in geography being undertaken by individuals than I have given credit for, but certainly in geographical periodicals, and in the bibliographies which are published annually, the amount shown is not large; neither is the number of authors as large as might be expected from the importance and interest of the subject and from the activity of those centres where geography is seriously taught. There seems to be no reason why individual research on true scientific lines should not be as active in geography as it is in geology, botany, zoology, or any other branch of knowledge; and, just as in these, the real advance in the subject is dependent on such investigations rather than on travels and explorations in little-known lands, unless these, too, are carried out scientifically and by thoroughly trained observers who know the problems which there await solution, and can read the evidence which lies before them on their route.

If research in these directions is being actively prosecuted, but the appearance of its results is delayed, let us seek out the retarding causes, if there be any, and increase any facilities that may be desirable to assist individual efforts.

Short technical papers of a thoroughly scientific character, such as are the outcome of serious individual research, are, of course, not suitable for those meetings of geographical societies where the majority of the fellows present are not scientific geographers, but should be presented to small meetings of other workers in the same or allied fields, where they can be completely criticised. The reading, discussion, and the publication of papers of this class are for geography a great desideratum, for it is in them and by them that all real advance in the subject is made, rather than by tales of travel, however interesting, if these are not the work of one trained in the subject, having a knowledge of what he should observe, and of what his predecessors have done in the same field. The regional aspect of geography in the hands of its best exponents has given to young geographers a wide and comprehensive outlook on the interaction of the various geographical factors in a region, the responses between the earth's surface and the life upon it, and the control that one factor may exercise upon another. In this form the fascination of geographical study is apparent to everyone, but I sometimes wonder whether the exposition of such a regional study by one who is thoroughly master of the component factors, having a first-hand knowledge of all the material involved, and knowing exactly the trustworthiness of each portion, impresses sufficiently upon the student the necessity of personal research into the details of some problem or phenomenon in such a way as to gain a real working acquaintance with them; or does it, on the other hand, tend to encourage generalisations based on descriptive accounts which have not been verified, and where coincidences and similarities may be accepted without further inquiry as evidence of a causal connection which may not really exist? I imagine that the student may be attracted by the apparent simplicity of a masterly account of the geographical contents and responses involved, and may fail to realise that geographical descriptions, even though technically phrased, are not the equivalent of original quantitative investigation, either for his own education or as a contribution to the subject.

For these reasons I believe that societies can do far more good in the promotion of geography as a science by assisting competent investigators, by the loan of books and instruments, and by giving facilities for the discussion and publication of technical papers, than by undertaking the investigation of problems themselves.

Among the earlier presidential addresses of this section some have laid stress on the importance of the recognition by the State of geography in education; others have represented the great part which the geographical societies have played in supporting and advancing the subject; others again have urged the fuller recognition of geography by educational institutions. I would on this occasion attach especial importance to the prosecution of serious research by individuals in any branch of the subject that is accessible to them, to the discussion of the results of such work by others of like interests, and to the publication of such studies as having a real value in promoting the advancement of scientific geography.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—Mr. H. G. Plimmer, F.R.S., has been appointed professor of comparative pathology in the Royal College of Science, South Kensington.

FOUR lectures will be delivered at Gresham College, E.C., on "Typhus Fever and Cerebrospinal Meningitis," on October 5–8, by Dr. F. M. Sandwith, Gresham Professor of Physic. The lectures are free to the public, and will begin each evening at six o'clock.

A SERIES of lectures on "The Wonder-workers of the Soil" will be given in the fellows' rooms of the Royal Botanic Society of London, Regent's Park, N.W., on October 4, 11, and 18, by Prof. W. B. Bottomley. The lectures will deal with:—(1) soil bacteria in relation to soil fertility; (2) the story of soil inoculation; (3) the discovery of auximones (accessory food substances).

BY the will of Mr. W. Jackson, engineer, of Aberdeen, who left, in addition to real estate, personal estate in the United Kingdom valued at 77,052*l*., one-half of the ultimate residue of his property, which is subject to his wife's life interest, is left for the establishment of a chair of engineering in the University of Aberdeen, any balance being then applied for charitable or benevolent objects in Aberdeen.

THE Manchester Municipal School of Technology publishes separate prospectuses of its part-time courses, and those in chemistry and chemical technology and in mathematics, physics and natural science, have been received. The part-time courses include:—apprentices' day courses for engineers' and other apprentices whose employers allow them to devote one whole day per week to study; evening courses, involving attendance on three evenings a week for five years, and leading to the Associateship of the School of Technology; and other evening and part-time day classes for advanced study and research, in preparation for the external degrees of the University of London, in technological or trade subjects, in various branches of natural science, and in other subjects. Further particulars of the work of the college were given in NATURE for August 12 last (vol. xcv., p. 664).

THE new session of the Sir John Cass Technical Institute, Aldgate, E.C., which is especially devoted to technical training in chemistry, metallurgy, and physics, and in the artistic crafts, will commence on September 27th. The instruction in experimental science provides systematic courses for London University examinations in addition to the courses on higher technological instruction, which form a special feature of the work of the Institute. The curriculum in connection with the fermentation industries includes courses of instruction on "Brewing and Malting" and on the "Micro-Biology of the Fermentation Industries." A series of lectures dealing with the supply and control of power has been arranged. These will comprise lectures on "The Supply and Control of Liquid, Gaseous, and Solid Fuel," "Electrical Supply and Control," and "The Transmission of Power." In the department of physics a special course will be given on "Colloids," which will deal with the methods employed in their investigation and their relation to technical problems; also special lectures on "The Influence of Surface Tension on Chemical Phenomena." In the metallurgy department special advanced courses are provided on gold, silver, and allied metals, iron and steel, metallography and pyrometry, heat treatment of metals and alloys, and mechanical testing of metals and alloys.

THE calendar for the current session has reached us from the Merchant Venturers' Technical College, Bristol, in which the Faculty of Engineering of the University of Bristol is provided and maintained. The college aims at providing a sound, continuous, and complete preparation for an industrial career, and its work is carried out in a secondary school, in day classes, and in evening classes. The calendar gives much evidence of the success of the governors of the college in securing the co-operation and support of the employers of the district. Many engineering firms have expressed willingness, other things being equal, to give preference to students who have completed the full college course, and some are prepared to take students at reduced premiums, while others will waive premiums altogether. Many local employers exempt from overtime, on not more than three days a week, persons in their employ who attend the college evening classes. A list of such persons is sent to each firm at the beginning of the session, with a list of the nights on which they ought to attend the classes; and a monthly return of the attendances of the evening students belonging to each firm is also forwarded. The Board of Trade accepts attendance at the evening classes in engineering in lieu of a portion of the workshop service required from candidates for the Board's certificate of competency as engineer. In other ways, too, such as by gifts and loans of books and plant, the employers of labour are showing a growing interest in the useful and varied work of this important technical college.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, June 23.—Dr. A. Smith Woodward, F.R.S., president, in the chair.—Prof. Xavier **Stainier**: A new eurypterid from the Belgian Coal Measures. The discovery is recorded of a specimen of a new Eurypterus in the cores of a trial-boring for coal in Belgium. The fossil, which is in a satisfactory state of preservation, is described. A short description of the eleven Carboniferous species known up to the present is appended. The nearest form to the Belgian fossil seems to be a Pennsylvanian Eurypterus, which, nevertheless, is not identical with the former. The geological range and the evolution in time of the twelve Carboniferous eurypterids is discussed.—R. B. **Newton**: A fossiliferous limestone from the North Sea. The material was trawled from the floor of the North Sea. It presents no appearance of glaciation, so that its occurrence *in situ* seems to be highly probable. There is no record of a similar limestone from either England or Scotland. It is of highly siliceous character and full of marine shells, of which the Pelecypoda are the more prominent; there are fragments of wood in contact with the limestone which appear to show coniferous characters. Some twenty-three species of mollusca have been determined, all of which exhibit a southern facies, including a new dosiniform shell belonging to the genus Sinodia, the relationships of which are confined to the Indian Ocean regions of Southern Asia. Eighteen of the species trace their origin from the Vindobonian stage of the Miocene, ten may be regarded as extinct, whereas twelve still exist in recent seas. The majority of the species are fairly evenly distributed in both the Coralline and the Red Crag formations of East Anglia, although it is thought that the rock must be of older age than Red Crag. Additional support is given to this view, because such shells as *Arcoperna sericea*, *Tellina benedeni*, and *Panopaea menardi* are not known of later age in this country than the Coralline Crag. The occurrence also of extinct

gastropods, which are characteristic of the Upper Miocene or Messinian deposits of northern Germany, constitutes further evidence in favour of a greater antiquity for this limestone than that of the Red Crag; it is, therefore, considered to be of Coralline Crag age.—W. R. **Jones**: The origin of the tin-ore deposits of the Kinta district, Perak (Federated Malay States). Certain tin-ore-bearing clays occurring in the Kinta district have been described as being of glacial origin, and the tin-ore which they contain as having been derived from "some mass of tin-bearing granite and rocks altered by it, distinct from and older than the Mesozoic Granite" (that is, than the granite now *in situ* in the Kinta district). These clays are stated to have furnished a more valuable horizon on climatic evidence than can be afforded by limited collections of fossils in rocks far removed from Europe. The importance is urged of the origin of these clays in a country where, on one hand, they yield an important part of the world's output of tin-ore, and where, on the other, they have been used as the horizon on which to base the geological age of rocks which cover about a third of the surface of the Malay Peninsula. If of glacial origin, a vast tin-field remains to be discovered. The object is to show that all the tin-ore found in these clays is derived from rocks now *in situ* in the Kinta district; that it is not necessary to bring in glacial action to explain and to show that a simple interpretation may be given to the geology of the Kinta district. The sources of the tin-ore are:—(1) the stanniferous granite of the Main Range; (2) other granite outcrops known to carry cassiterite; (3) the granitic intrusions in the phyllites and schists; and (4) the granitic intrusions traversing the limestone. The angularity of the boulders and of the tin ore in some of these clays is due (1) to weathering *in situ* of the phyllites and schists, which then sink on the dissolving limestone underneath; (2) to soil-creep effecting the same result; (3) to the breaking up of the weathered cassiterite-bearing boulders in the alluvium. More than 90 per cent. of the ore worked in the Kinta district is obtained from mines situated at less than a mile from granite or from granitic intrusions.

ENGINEERING MATERIALS.

(1) *Materials of Construction: Their Manufacture, Properties, and Uses.* By Prof. A. P. Mills. Pp. xxi+682. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 19*s*. net.

(2) *The Strength of Materials: A Text-book for Engineers and Architects.* By E. S. Andrews. Pp. x+604. (London: Chapman and Hall, Ltd., 1915.) Price 10*s*. 6*d*. net.

(1) "MATERIALS of Construction," by Mr. A. P. Mills, is an excellent text-book covering a wide field, including cementing materials, masonry, bricks and clay products, ferrous and non-ferrous metals and timber. Generally a short historical statement is given, a list of applications in the arts, a well-illustrated description of manufacturing processes, an account of chemical, physical, and mechanical properties, and some statistics of American production. The information is based largely, but not exclusively, on American experience, but is not less interesting on that account. English readers will be glad to become acquainted with the very trustworthy results of tests obtained by the U.S. Bureau of Standards, the Structural Materials Laboratory of the U.S. Geological Survey, and the laboratory of the U.S. Forest Service, as well as the investigations of the active American Society for Testing Materials.

The treatise is very comprehensive. For instance, in treating cements, there are separate chapters on gypsum plasters, quicklime, hydrated and hydraulic limes, Puzzolan and slag cements, natural cements, Portland cement and concrete. Or again, in dealing with ferrous metals, chapters on pig iron, cast iron, malleable cast iron, wrought iron, steel, and the special alloy steels. There is adequate criticism of the processes, the tests, and the investigations described.

Only a few points of interest can be referred to. The researches of Le Chatelier, Törnebohm, and the Newberrys on the constitution of Portland cement are carefully summarised, and the chemical, optical, and thermal researches at the Carnegie Geophysical Laboratory at Washington, which on the whole confirm the results of Le Chatelier. Standard American tests for cement are given and the conditions influencing the results are discussed. Curiously, rather little is said of methods of testing. The diagrams of tensile strength of 1 : 2, 1 : 3, and 1 :4 cement mortars with sand graded to different fineness are instructive, and a constant relation of density and strength was observed. Diagrams of the ratio of compressive to tensile strength, based on an extensive series of tests of neat cement and cement mortars made for the U.S. Geological Survey, are interesting.

It appears that charcoal is used in the production of about 1 per cent. of pig iron in the United States. A brief account is given of electric furnaces, the product of which is claimed to equal in quality Swedish charcoal iron. It is stated that the electric furnace used for steel-making has already become a formidable rival of the crucible process, because it is able to make larger tonnages of tool steel of crucible quality at lower cost. It has also advantages in the production of alloy steels in that it need not be operated under oxydising conditions.

The mechanical properties of materials are shown by numerous graphic diagrams, which condense in small space a large mass of results. It is interesting that the U.S. standard specifications for iron and steel express the elongation per cent. in the form constant/(ultimate tensile strength). This is the adoption of the Tetmajer coefficient of quality in commercial testing. The deviation of this rule from the results of tests, which is not inconsiderable, is shown in Fig. 263. Prof. Hatt's results on the ratio of elongation and work of rupture in static and dynamic tests will be new to most English engineers. The treatment of fatigue is imperfect.

(2) "Strength of Materials" is properly understood to relate to the methods and results of the experimental investigation of the physical constants of materials of construction and the testing of the quality of supplies from different sources. It touches, on one side, the mathematical theory of elasticity, and on the other, applications in the theories of machines and structures. In the volume by Mr. Andrews all these branches of applied mechanics are treated together, and strength of materials in the restricted sense is rather perfunctorily dealt with. Riveted joints, beams, struts, shafts, flat plates, and rotating discs are discussed mainly from a purely mathematical point of view, graphic methods being largely employed.

No doubt the book will be useful to students and young engineers, especially because so many special cases are worked out algebraically and numerically in detail. At the same time it is doubtful if the author has quite digested his reading. On some fundamental points he is obscure. Discrepant solutions are placed side by side, and the student left to his own resources or put off with "we believe." Thus two theories are given of the simple case of a rectangular reinforced beam. In a numerical example the bending moment comes out three times as great by one as

F

by the other. The calculation of deflections by "Mohr's method" is good. But the whole subject would have been much clearer if the well-known principle had been explained, that the load, shearing force, bending moment, slope and deflection curves form a series each derived from the next by graphic integration.

The phrasing is often loose. "For most metals . . . the yield point is reached when there is a sudden large increase in strain." Only in a few metals is there a yield point in this sense. The whole account of fatigue is unsatisfactory. The author is in confusion between the old view of Claxton Fidler, who must always be spoken of with respect, who believed that the Wöhler effect was purely the result of dynamic action, and what is now clear that there is a real "fatigue" due to slip fissures developing at first slowly, but at last rapidly and locally. It is true that American engineers have mixed up an allowance for fatigue and for impact in the case of railway bridges. But that is wrong in principle. Strictly, the fatigue allowance is not one of the factors which make up the factor of safety, but like the yield point, the fatigue limit is a stress not to be exceeded when the total stress due to load, impact, and contingencies has been calculated. To the author "the subject is still full of difficulties" (p. 89). At this late date it is odd to read "we will make the following assumptions in developing *our* theory of torsion" (p. 317). The use of alignment charts in designing springs seems new (p. 342).

PLANTS OF FORMOSA AND THE RIVIERA.

(1) *Icones Plantarum Formosanarum nec non et Contributiones ad Floram Formosanam.* Vol. iv. By B. Hayata. Pp. vi + 264 + xxv plates. (Taihoku: Government of Formosa, 1914.) n.p.

(2) *Flowering Plants of the Riviera.* By H. Stuart Thompson. With an Introduction on Riviera Vegetation. By A. G. Tansley. Pp. xxix + 249. (London: Longmans, Green, and Co., 1914.) Price 10*s.* 6*d.* net.

(1) THE fourth volume of Dr. Hayata's great work on the flora of Formosa, modestly described as "materials for a flora of the island," based on a study of the collections of the Botanical Survey of the Government of Formosa, contains descriptions of 285 species, of which no fewer than 167 are new to science, including a new orchid genus Arisanorchis of considerable interest as adding another member to the small list of leafless saprophytes in this family. Moreover, thirteen genera are mentioned as new to the Formosan flora, these including such well-known genera as Aconitum, Cornus, and Hydrocharis. This volume brings the total number of species of the flora up to more than 3000, and we are promised several more volumes, indicating the remarkable floristic richness of the island.

In his interesting introduction the author suggests two resolutions regarding the description of new species of plants for consideration at the meeting of the International Botanical Congress fixed for the summer of 1915 in London, "if the present overwhelming war is then over." This introduction is dated August 31, 1914. As usual in Dr. Hayata's works, the illustrations are numerous and beautifully executed, and the whole reflects the greatest credit upon the author and upon the enlightened Government of Japan. It is worthy of note that the author has preferred to follow the classification of Bentham and Hooker rather than that of Engler and Prantl, and this appears a wise choice, for although the former system may be in various respects inferior as a method of presenting the genetic affinities of the families of plants, the latter is far from being a natural system, and is constantly undergoing modification. This being the case, adherence to the older system, for purposes of ready comparison between different floras, is perhaps on the whole the best course to adopt.

(2) The author's previous volumes on alpine and subalpine plants fully demonstrated his facility for popular yet accurate plant description, and he has had long personal acquaintance with the region here dealt with. The flora is arranged on the Bentham and Hooker system, thus facilitating comparison with French works on the flora of the Riviera, in which the system used is practically identical with the English one. The author has spared no pains to make it easy for those with even a slight knowledge of botanical terminology to identify the plants described, for the actual descriptive part is preceded by synopses of family characters and keys to the tribes and genera, and there is also a full and clear glossary of terms used. As the subtitle ("A Descriptive Account of 1800 of the More Interesting Species") indicates, the book does not profess to be an exhaustive "flora," but though the botanist may regret the incompleteness which is particularly noticeable in the case of some of the larger families and genera, these cases nearly all refer to groups which the non-professional botanist would find unattractive. The author wisely refrains from the attempt, which mars many books of this scope, to manufacture so-called English names for species.

The plates, both coloured and plain, are exceedingly good, and a valuable feature of the book is the interesting but disappointingly brief introduction by Mr. Tansley, which deals with the ecology

of the Mediterranean vegetation and the various plant communities represented in the Riviera. However, brief as it is, this introduction gives a remarkably clear picture of the vegetation, such points as the relations of soils and the striking effects of exposure and shelter being well brought out. Those who hope to visit or revisit this beautiful region, when happier times arrive, should have Mr. Thompson's book on Riviera flowering plants.

TWO HANDBOOKS OF EXPLORATION.

(1) *Stories of Exploration and Discovery.* By A. B. Archer. Pp. x + 198. (Cambridge: At the University Press, 1915.) Price 2*s.* 6*d.* net.

(2) *The North-West and North-East Passages, 1576–1611.* Edited by P. F. Alexander. Pp. xx + 211. (Cambridge: At the University Press, 1915.) Price 2*s.* 6*d.* net.

(1) MR. ARCHER'S book supplies a short history of exploration in simple language. It opens perhaps a little uncertainly on the importance of the Eastern Mediterranean as the earliest known centre from which knowledge of the world was extended outwards. "The Egyptians used boats on the Nile, and perhaps along the coasts of their country, but probably the first serious navigators were the people of Phœnicia"—this, in the light of recent research concerning early Mediterranean peoples, is not a wholly satisfactory summary. The subsequent chapters are handled more firmly, and the rather difficult task of balancing between topographical correlation and historical sequence is judiciously carried out. The final chapters on modern polar exploration, however, are less successful. They maintain the interest to the student, but sometimes a point is missed: thus, it is an unfortunate version of the dramatic encounter between Nansen and Jackson which states that Nansen and Johansen "reached the south of Franz Joseph Land, where to their delight a relief ship was waiting." There is a short bibliography of easily-accessible books of reference, and a good index is provided. There are also some rough but sufficiently clear maps, and some clever adaptations of old maps.

(2) Mr. Alexander's book contains a series of extracts from original narratives of voyages in search of the north-west and north-east passages, together with an explanatory introduction, a chronology of important dates in geographical discovery generally, and notes. The extracts are from George Best's account of Frobisher's first and second voyages, from the narratives of Davis's three voyages and of Hudson's last voyage, and from de Veer's account of Barents's third voyage; which is supplemented by an account of the discovery, in modern times, of relics of that voyage. Hakluyt, Purchas, and the Hakluyt Society's second edition of Phillip's translation of de Veer have been drawn upon. The modernising of these texts, so far as necessary, has been carried out without any of the charm of the original being lost. It is this peculiar charm which makes these narratives most attractive to the student for whom these volumes are designed—for it should be added that this book belongs to a series to be known as "Cambridge Travel Books," of which another, "The Earliest Voyages Round the World," is stated to be in the press. The book is excellently produced, and the original illustrations reproduced are as instructive as they are amusing; there are also a few explanatory maps. It can only be a question whether in a book of this compass, designed for the purposes indicated, there should not be shorter extracts from more narratives, but no doubt it would be difficult, if not impossible, to carry out such a plan and maintain the interest of the originals.

OUR BOOKSHELF.

Aids to the Analysis and Assay of Ores, Metals, Fuels, etc. By J. J. Morgan. 2nd edition. Pp. viii + 138. (London: Baillière, Tindall and Cox, 1915.) Price, cloth, 3*s.* net; paper, 2*s.* 6*d.* net.

THE first edition of this capital little book has been useful to students of evening classes for a number of years, and the appearance of the second edition will be welcome to their instructors in metallurgical analysis. The general arrangement is good, and has been maintained unchanged, but the book has been considerably enlarged. In addition to descriptions of the assay of the ores of the common metals and of the complete analysis of commercially impure metals, sections are devoted to special steels and other alloys, fuels, furnace materials, and slags. There is also some account of the analysis of the by-products of coke-ovens. The characteristic of the book is that as a rule only one method of determination is given in each case, but the methods are well chosen as having stood the test of time, and the descriptions are concise and accurate. Little is said about apparatus and reagents; there are few illustrations, and in general the book seems to be intended rather to remind students of what they have been taught than to take the place of laboratory demonstration. In cases where the more expensive standard works on analysis and assaying are inaccessible, this handy volume will be found to take their place with scarcely any disadvantage. It is small enough to slip into the pocket.

Alignment Charts: their Principle and Application to Engineering Formulae. By E. S. Andrews. Pp. 32. (London: Published for James Selwyn and Co. by Chapman and Hall, Ltd.) 1*s.* 3*d.* net.

ALIGNMENT charts have been used to some extent by engineers in recent years, and are capable of being employed to a much greater extent. The

method was developed very largely by Prof. Peddle, of the Rose Polytechnic Institute, U.S.A., and his method of treatment has been followed by the author of the little book before us, with some variation in details. In this system of plotting scales of the variables involved are set off along parallel lines, and a straight-edge laid across the lines enables one of the variables to be determined when the others are given. The author describes methods to be followed when there are three, four, or more variables, and gives illustrations of the plotting of reinforced concrete column, boiler shell, steel beams, shafts, and other engineering formulæ.

Most of the illustrations are clear and easy to read; Figs. 1 and 2 are exceptions, the lettering and printing being poorly executed. There are very many problems of a repetition character in engineering, and much time can be saved by charts of this kind. There is also less risk of error in the results, once the chart has been correctly drawn. We can commend the book to engineers who wish to make themselves acquainted with this labour-saving device.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Mathematical Printing.

YOUR remarks in NATURE (September 16, p. 79) relating to the important suggestions on mathematical printing recently circulated by the London Mathematical Society, are confined to the examination of special points, in the light partly of application to the special case of an analytical memoir on dynamics of aeroplanes.

It is worth while to direct special attention to what is perhaps the main recommendation, for examples of its disregard are still conspicuous. The introduction of the notation of the solidus or oblique bar for fractions has had much to answer for, especially in this country, on account of its use in excess—for example, in reducing long formulas to the deal-level of a single line, thus obscuring their structure without any compensating gain. As originally revived by Sir George Stokes, and largely adopted on his suggestion, the intention was to render possible the printing of brief expressions isolated in the current text or elsewhere, without disturbing the line; its use for reducing a formula already specially set out, and involving a sum of fractions, to a single line of type, is usually to be deprecated.

The suggestion to replace the dot over a letter, the Newtonian symbol of its fluxion, by an accent following it, was put forward, doubtless with regret, as the lesser evil. If only printers would provide special types with the dot attached for the small number of letters likely to be thus affected, no change would be necessary.

Cambridge, September 24.

Palæolithic Man in South Africa.

I HAVE read in NATURE of August 5, just received, Mr. F. W. Fitzsimons's letter referring to the discovery of Palæolithic man in South Africa. I would not trouble you with these lines were it not that many of its statements are erroneous. Moreover, owing to my name being mentioned in connection with a detailed examination which is being carried out in this museum, it might be thought that I am in part responsible for the conclusions which Mr. Fitzsimons enumerates. As a matter of fact, I informed him, when first the skull was sent to us, and again some nine months ago, that the fragment was not referable to the Neanderthal type. There is, therefore, no more justification in the statement he makes that there is "a close resemblance in shape, thickness, and measurements" of the Boskop to the Neanderthal than in his generalisation on the origin of the Palæolithic implements in South Africa, or in the state of mineralisation of the relic—"The skull is as completely fossilised as the Karoo fossil reptiles," which are Permian and Triassic.

The result of a preliminary investigation of the skull by our palæontologist will be read shortly before the Royal Society of South Africa. Until then I cannot give any details beyond referring those interested in the subject to a short note by Prof. Boule in *L'Anthropologie* (vol. xxv., September–December, 1914, p. 595).

L. PERINGUEY.

The Aurora Australis of June 17, 1915.

IT is interesting to learn, as a complement to the description of the Aurora Borealis by Prof. Barnard in NATURE of July 15 as accompanying the magnetic storm of June 17, 1915, that a display of aurora was also observed in the southern hemisphere. My correspondent, Mr. W. E. McAdam, writes:—"Upon that day (June 17) there was an exceptionally fine display of the Aurora Australis visible all over New Zealand. Here at Dunedin it commenced at 7.30 p.m., and lasted till midnight. The glow in the southern horizon was quite uncanny in effect, producing the illusion that the sun was about to rise in an impossible quarter of the sky, and at an impossible hour. I have been resident in the Southern Hemisphere off and on for over fifty years, and have never seen anything to equal this last display of the Aurora Australis, a somewhat rare phenomenon in the latitude of Dunedin, 46° south."

A. L. CORTIE.

Distances at which Sounds of Heavy Gun-firing are Heard.

BEING much interested in the question of the distance of propagation of the sound of the firing of big guns, I should be much obliged to any readers of NATURE who could send me some personal observations on the matter, or let me know whether (and when and where) any notices on the subject have been published. Exact references are wanted, as I should try to get the papers containing the information. The gun-firing from the Belgian coast is probably heard in England at times. How far inland? All information will be gratefully received by me.

Nodules on the Intermediate Bladderwort.

MR. H. EVANS (NATURE of September 23, p. 88) should refer to Hooker's "Student's Flora," p. 311, Utricularia, "propagated by hybernacula"; and to Babington's "Manual of Botany," p. 339, *Utricularia intermedia* "increasing by buds at the end of the shoots and seldom flowering."

ELEONORA ARMITAGE.

Dadnor, Ross, Herefordshire, September 25.

THEORY AND PRACTICE OF FLYING.[1]

THE present notice refers to three new books on the theory and practice of flying. Although dealing with the same general subject, the ground covered by each is almost entirely different from that of the other two, and each has its own special interest.

"Aeroplanes and Dirigibles of War" deals with the uses of aircraft in the present war and with the methods of repelling aircraft attack by fire from the ground; the work contains very little technical matter, no attempt having been made to enter into details of construction. As showing the part which aircraft is playing in the world-war, the book can be read and appreciated with or without technical knowledge of aeronautics.

The other books under notice are largely technical, referring to aero-engines and to aeroplanes respectively. In the first of these, details of engines suitable for use in aeronautical work are shown with numerous illustrations; there is little theoretical matter, and scarcely any aerodynamics. The book on aeroplanes is, however, almost entirely devoted to aerodynamics, and summarises the important features as affecting the aeroplane so far as they lie within present knowledge. Having said so much generally, the further more particular notes may be of interest:—

(1) The book opens with interesting chapters on the history and development of free ballooning, tracing the military use of balloons back to 1884 and incidentally claiming for the British Government "superiority and initiative." In spite of more recent developments the author says that the use of balloons is still so important that no one of the belligerents will seriously consider their disuse. Passing from balloons to dirigibles, the early struggles of Count Zeppelin with his enormous rigid airships naturally receive much attention. Other types, including the Parseval and Astra-Torres non-rigid airships, come under review, but the author says of the Zeppelins that they have given airship supremacy to Germany. As a somewhat curious offset to this, the author quotes with approval a decision of the American military authorities that "dirigibles are not worth their cost as offensive machines," a decision which may after all prove to have been too sweeping.

After reading these early chapters, the section on aeroplanes is disappointing. In respect to British military machines in particular the author appears to have been singularly misinformed. As an instance of this, it is stated that the BE type of aeroplane has a maximum speed of 40–50 m.p.h., and to anyone acquainted with the technical flight journals such a statement is patently wrong. As a matter of fact, the lowest flight speeds are of the order of those mentioned, whilst the highest were more nearly 70–80 m.p.h. at the beginning of the war.

Coming to anti-aircraft guns and bomb-dropping the book again becomes interesting. One of the illustrations reproduced in Fig. 1 shows a mobile anti-aircraft gun as manufactured by Krupp. Some of these guns are said to throw a shell weighing 40 lb. to a height of 6000–8000 ft., forcing the aviator to similar heights for safety. From such heights the accurate dropping of bombs is a task of some difficulty, and success is often attained only by the pilot running the risk of destruction by shell-fire at much lower altitudes.

FIG. 1.—The latest Krupp anti-aircraft gun, showing novel disposition of wheels. From "Aeroplanes and Dirigibles of War," by F. A. Talbot.

The author concludes with an expression of his opinion that aerial activity will increase with the duration of the war, a prediction which is already being justified by events.

(2) The most interesting and useful part of this book is the description in detail of a number of engines used in flight. The descriptions occupy about three-quarters of the whole and range from

[1] (1) "Aeroplanes and Dirigibles of War." By F. A. Talbot. Pp. xi+283. (London: W. Heinemann, 1915.) Price 3s. 6d. net.

the 25 h.p. Anzani, with which Blériot first flew the Channel, to some of the more modern engines of 200 h.p. The growth of the art of flying is strikingly illustrated by the fact that whilst 25 h.p. was a useful size of engine in 1909, no present-day aeroplane, other than those for school purposes, has a horse-power less than 80, whilst many considerably exceed this. The celebrated Gnome engine, by means of which Farman and Paulhan achieved their early successes, is described very fully. The power was then a nominal 50 h.p., but really only 42 h.p., but Fig. 2 shows a much larger model weighing only 540 lb., whilst developing 180 h.p. The complication of cylinders which is essential for light engines is most clearly shown in this illustration.

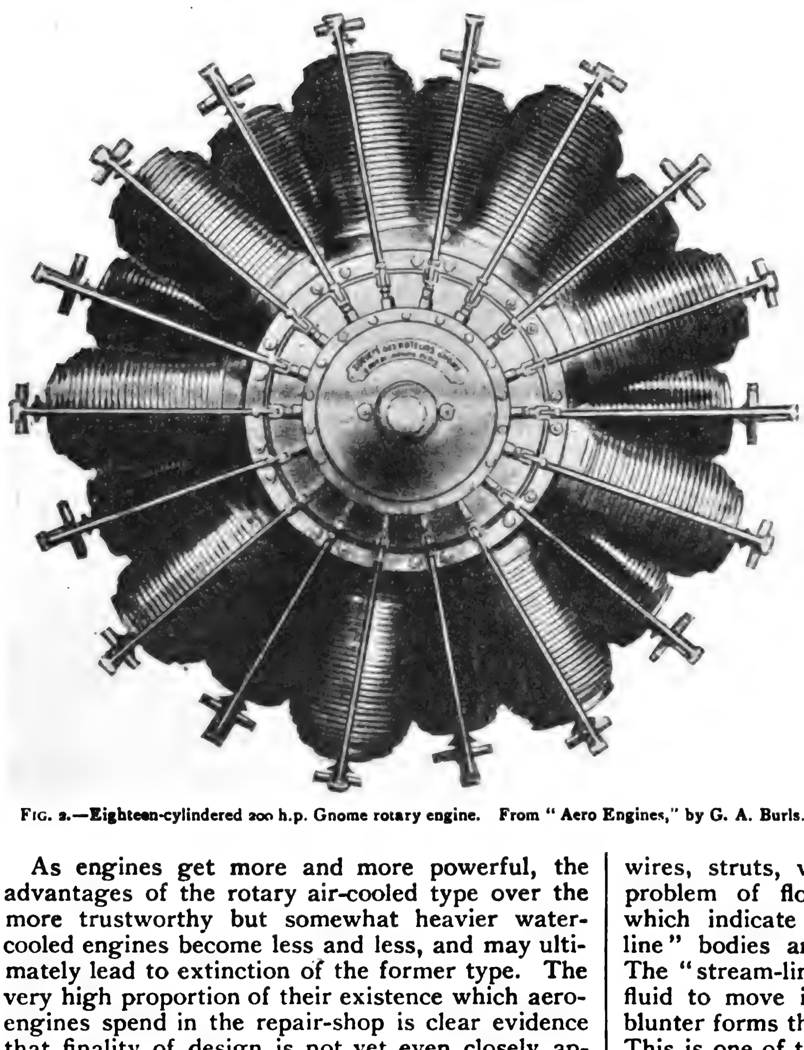

FIG. 2.—Eighteen-cylindered 200 h.p. Gnome rotary engine. From "Aero Engines," by G. A. Burls.

As engines get more and more powerful, the advantages of the rotary air-cooled type over the more trustworthy but somewhat heavier water-cooled engines become less and less, and may ultimately lead to extinction of the former type. The very high proportion of their existence which aero-engines spend in the repair-shop is clear evidence that finality of design is not yet even closely approached, but there is reason to hope that the introduction of large water-cooled engines will considerably reduce the time of repair without the disadvantage of greater weight.

The earlier part of the book contains theoretical matter relating to the working of hot-air engines and follows standard lines in most respects. After contrasting the weights of internal combustion engines, the air-cooled engine of about 3 lb. per b.h.p. with the workshop engine weighing 200 lb. per b.h.p., the author proceeds to a discussion of the working cycle. By some extraordinary calculation he concludes that an engine using the Carnot cycle would weigh 17 tons per b.h.p.; one feels that this is overdone, and that part of the trouble at least is not legitimately laid on the Carnot cycle, but should be borne partly by the designer and partly by the calculator.

Excursions into aerodynamics have already been stated to be few; they are also mostly unfortunate. It is stated that a reduction of gross weight of an aeroplane improves the gliding angle, whereas the two are independent, the effect of reducing the weight being to reduce the flying speed at the same gliding angle. A little later occurs a meaningless statement that "the power, *caeteris paribus,* varies as the cube of the air speed, etc." What the Latin expression covers it is not easy to see; for any given aeroplane the horse-power at first decreases as the speed increases, becomes steady, and then gradually increases. No power of the speed at all can be stated in such general terms. On the same page there occurs a conspicuous error in applying the principles of relative motion to flight in a gale.

These are, however, minor defects which can be put right in later editions, and the information on engines gives the book a right to the bookshelves of all serious students of aviation.

(3) This work is a summary of the dynamics of the aeroplane, and has apparently aimed at the suppression of detail in order to make the important features clear. The early part of the book is based on the results of tests at the various aerodynamical laboratories, on the lift and resistance of wing forms, and the resistances of wires, struts, wheels, etc. In dealing with the problem of flow, photographs are reproduced which indicate the difference between "stream-line" bodies and forms having high resistance. The "stream-line" body is shown as allowing the fluid to move in towards the tail, whilst in the blunter forms the tail region is occupied by eddies. This is one of the more clearly exhibited forms of the effects of viscosity, but in later photographs, showing the velocity of the fluid at any point, the very great difference between the flow round "stream-line" bodies and those of mathematical calculation is almost equally striking.

After discussing the effects of changes of sections of the wings on their efficiency, a few aeroplanes are described, with particulars as to

leading dimensions and weights, and such data is then used to show how the performance of an aeroplane may be calculated. The calculation involves the use of aerodynamical data already described, and also means of estimating the performance of propellers. The usual theory of propeller design is given, and although this now appears to be in need of improvement, the results obtained by its use have been of very great value. In addition to the calculations relating to equilibrium a chapter is included on the question of stability.

The book closes with a short description and discussion of aero-engines, and the whole appears to be very sound. The impression is left, however, that in the attempt to be concise too little assistance has been given to the reader. Like the book on aero-engines, by the same publisher, the production is excellent, the illustrations being particularly clear.

THE VISIBILITY OF DISTANT OBJECTS IN WARFARE.

THE long range of weapons employed in modern warfare has given importance to the study of the appearance of distant objects. A constant contest is taking place between the observer trying to locate the position and numbers of the enemy, and the observer who endeavours by all possible means to conceal these factors.

Generally speaking, an object becomes indistinguishable when its brightness and colour are identical with its surroundings. For this reason such colours as grey and khaki, which blend well with the surroundings, are preferred for modern uniforms. Yet their effectiveness in this respect depends on the nature of the ground over which troops are moving. Khaki is doubtless difficult to distinguish amidst sandy wastes; grey or green might be better against grass or foliage. Of all colours, red is the most conspicuous at a distance. Not only is it the colour which presents the most vivid contrast with the ordinary background, but there appear to be certain physiological factors which accentuate this impression. For example, it is well known that the central region of the eye (which is mainly used for the observation of distant objects) is highly sensitive to the red end of the spectrum and correspondingly insensitive to blue and green. It has also been alleged that, owing to the eye lens not being achromatic, most people find it difficult to focus distant blue and violet light; and that such objects readily merge in the landscape because their outlines are hazy and blurred. Skilful gardeners in designing a flower-bed arrange the blue and lilac flowers in the foreground when possible, and rely on vivid red and orange blooms for a distant effect.

It is known, however, that in a dim light the conditions obtaining in full daylight do not apply. In a feeble illumination the eye becomes more or less colour-blind and is highly insensitive to red, which appears dead black, whereas green and blue objects appear an uncanny grey. A party of men in grey-green uniforms advancing across a grass field in twilight would therefore be extremely difficult to detect.

All this suggests that the problem of selecting an inconspicuous uniform is a complicated one, especially when it is borne in mind that it is also important that bodies of men, besides being inconspicuous to the enemy, should be clearly visible to their own side. It has been suggested that this condition might be secured by differentiation in the colouring of the front and back of the uniform.

It is interesting to observe that on several occasions during the present war scouts have taken special steps to accommodate the colour of their clothing to the surroundings. For example, it is stated that the Germans provided some of their men with white uniforms in order to match the snow in the Polish campaign, and that the Turkish snipers in Gallipoli painted their hands and faces green so as to be indistinguishable amidst foliage.

It is clearly more difficult to secure resemblance to surfaces which are constantly changing, such as the sky and the sea. But there is a second principle which can also be used to secure inconspicuousness in these circumstances, namely, what may be termed the "patchwork" principle. This is based on the experience that the outlines of an object may be rendered difficult to distinguish by breaking up its surface with stripes and patches. This method has been applied to aircraft and hydroplanes, and to forts and temporary defences of various kinds. Besides painting the hulls and funnels of warships a slaty-blue or "battle-grey," experiments have been made with mottled patches of black and irregular serpentine black lines painted on a grey background. Some experiments in this direction recently carried out in the United States Navy are said to have been very successful, and it may be only a question of time before Dreadnoughts are rendered practically invisible at the long range of modern sea-battles.

A combination of patchwork and imitation of surroundings may also be applied with good results in order to conceal aerodromes and similar objects. For example, if the adjacent ground is cleared and the grass is scraped away at intervals, leaving bare patches, and if the aerodrome itself is painted a patchwork of brown and green, identification from above becomes very difficult. Yet another instance is furnished by the recent correspondence in the *Times* regarding the colour of sandbags. It is stated that the Germans insert black sandbags at intervals among those of lighter tint. An officer at the front wrote:—". . . It was the first thing I noticed about the German trenches. Their patchwork device made it impossible to spy their loopholes, whereas ours take a long time to build and then are easily seen."

A device such as this, which would apparently save a considerable number of lives in a long campaign, is well worth attention.

There remains one other possible device for concealing objects which, although difficult to

apply, is probably the most perfect of all when realisable. This is to make use of mirror or semi-mirror surfaces which reflect their surroundings and thus automatically imitate them. Such a device would be applicable in any surroundings.

The chief instance known to the author of the use of this method is afforded by the latest Zeppelins, which are reported to have a coating of bright aluminium powder, which reflects the sky and makes the vessel very difficult to detect at any considerable height. For aircraft flying at a height the problem of concealment is a particularly difficult one, as whatever pigment is adopted the framework is seen silhouetted against the bright sky. It is possible that by making use of reflecting surfaces, in addition to the other devices mentioned, this contrast could be considerably lessened. If to a noiseless engine could be added the quality of practical invisibility, aircraft would become very much more dangerous offensive machines than at present.

Such problems as those mentioned above seem to deserve careful scientific study. Methods of concealment may do much to save the lives of combatants. Moreover, the utility of all vessels employed for scouting purposes, whether aircraft, motors, or submarines, depends to a great extent on their escaping detection. It is therefore surely well worth while to follow up any train of research which offers any promise of approaching invisibility in the future. J. S. D.

PROF. W. H. H. HUDSON.

We greatly regret to record the death, on September 21, of Prof. W. H. H. Hudson, at the age of seventy-six years. Born in London, he graduated as Third Wrangler in 1861. He was then fellow and lecturer of St. John's College until 1882, when he was appointed professor of mathematics at King's College, London. There, and also as professor of mathematics at Queen's College, Harley Street, he worked until his retirement about twelve years ago.

It is as a lecturer, and as a constructive reformer of the teaching of elementary mathematics that Prof. Hudson's vigorous influence will long be felt. Of his numerous pupils many became teachers, and the improvements in modern methods of teaching must be largely due to his inspiration. He edited Barnard Smith's "Arithmetic," published notes on dynamics, gave various addresses on the teaching of elementary mathematics, contributed to the mathematics of meteorology with a theory of anemoids, and did much to promote order and economy in the study of mathematics by adding to its vocabulary terms now generally found useful. He was an active member of the conference which reported to the London County Council on the teaching of arithmetic; of the councils of the London Mathematical Society and of the Mathematical Association; and of the governing body of Newnham College, in the welfare of which (as of the education of women generally) he was warmly interested.

Prof. Hudson's principles received remarkable vindication in the record of his family. By the tragic death on Snowdon, in 1904, of his only son, Cambridge lost one of its most brilliant Senior Wranglers, and perhaps the most widely accomplished. The researches of Ronald Hudson in Kummer's "Quartic Surface," published posthumously, placed him in the front rank of geometers. The three surviving daughters of Prof. Hudson have all distinguished themselves as mathematicians.

Few men intimate with the austerities of the most difficult of subjects can have made a wider circle of personal friends than did Prof. Hudson. He had the gift of humour and sympathy which endeared him to all those he taught. He enjoyed travel and recreation to the end of his days, and within the boundaries of mathematical study he knew how to find both.

NOTES.

The Rev. Dr. E. W. Barnes, fellow and tutor of Trinity College, Cambridge, has been appointed to the mastership of the Temple. Dr. Barnes is in his forty-first year, and had a brilliant career at Cambridge. He went up to the University as a scholar of Trinity College, and in 1896 was bracketed second Wrangler. A year later he took a first class in the first division of the Mathematical Tripos, part ii., and was first Smith's prizeman in 1898, besides being president of the Union. He was elected a fellow of his college in the same year, and was an instructor at the Royal Military Academy, Woolwich, in 1898–99. He is the author of various memoirs and papers on Gamma functions, integral functions, linear difference equations, and related mathematical subjects.

The Victoria Cross is given for conspicuous courage in the face of the enemy: and, if we want a good example of such courage, we have it in the English nurse, at the American Hospital at Neuilly, who inoculated herself with a pure culture of the bacilli of gas-gangrene, that she might help the discovery of the best treatment of that disease. We rejoice that she now is out of danger of death. The annals of medicine record many similar instances of self-devotion, and doubtless there are others which have gone unrecorded. They have not always been of use to mankind: John Hunter, for example, inoculated himself with the virus of one of the venereal diseases, but drew a wrong conclusion from the results of the experiment. The amazing self-experiments with yellow fever, in Camp Lazear, were happily not in vain. The protective treatments against cholera, plague, and typhoid fever were, of course, well tested by their discoverers on themselves before they were put to national uses. A good essay is waiting to be written on the whole subject of self-experimentation. Lord Moulton, in his evidence before the Royal Commission on Vivisection, discusses the ethics of it, and he does that very well. But formal ethics scarcely touch the case; the self-experimenter, in the presence of the enemy, the germs, the havoc they work on men, women, and children, "sees red," and behaves

accordingly. We salute with reverence this big-hearted Englishwoman, but we beg of her that she will not do it again.

WE regret to learn of the death, on September 8, at eighty-one years of age, of Dr. Ugo Schiff, professor of chemistry in the R. Istituto di Studi Superiori, Florence.

DR. C. H. WING, professor of chemistry at Cornell University from 1870 to 1874, and at the Massachusetts Institute of Technology from 1874 to 1884, died recently at the age of seventy-nine.

THE death is announced, in his fiftieth year, of Dr. K. E. Guthe, professor of physics at the State University of Iowa from 1905 to 1909, and at the University of Michigan since the latter date. A native of Hanover and educated in Germany, he went to the United States in 1892. He was a member of the jury of awards (electricity) at the St. Louis Exposition in 1904, and had made several contributions to the literature of physics.

NATURALISTS, and especially ornithologists, throughout the British Islands are the poorer for the sudden death on September 15 of Mr. R. M. Barrington, of Fassaroe, Bray, Co. Wicklow. Though in his sixty-seventh year, he was still full of activity and of enthusiasm for his favourite studies. An admirable example of the "all-round" naturalist, Mr. Barrington will be especially remembered for his work on the migration of birds. From 1880 he collected specimens forwarded to him by lightkeepers around the Irish coasts, and the results of these observations were published in a substantial volume in the year 1900. Many birds were thus recognised for the first time as Irish species—such as the yellow-browed warbler, the aquatic warbler, the barred warbler, Pallas's grasshopper warbler, the short-toed lark, the shore-lark, the mealy and Greenland redpolls. The specimens accumulated were either passed on to the National Museum in Dublin, or preserved in Mr. Barrington's beautifully kept private museum at Fassaroe, in which he took great pride and pleasure, and which he was always ready to show to friends, expounding the while from the wide experience with which his memory was stored. He was a keen botanist, having in his younger days paid especial attention to the Alpine plants of Ireland. He threw himself heartily into many enterprises for extending biological knowledge and interest, having been one of the founders of the Dublin Naturalists' Field Club, and a valued member of council of the Royal Irish Academy, the Dublin Society, and the Zoological Society of Ireland. To his wide knowledge of natural history there were added a personal charm and a kindly humour which will make the memory of his friendship a high privilege.

IT has been found that at the present time there are three main causes which delay the production and repair of aircraft and their parts, namely, lack of co-ordination between those engaged in aeroplane construction, difficulties of finance, and shortage and wastage of labour. To remedy these disadvantages, it is proposed to establish a central body under the title "Aeronautical Production Committee" or some similar name, the functions of which will include the promotion of co-operation and co-ordination in the aeronautical industry, the provision of technical assistance otherwise unobtainable for financial institutions, and the development of arrangements for the better utilisation of the existing labour and the training of as many men for aeronautical work as the situation demands. It is estimated that an expenditure of about 100*l.* per week would enable the committee to supply the Army and Navy with seven more aeroplanes every week, and it is suggested that the sum might be raised partly by a Government subsidy, partly by a small fee charged to the makers for the benefits they would derive from the central bureau, and partly by voluntary subscriptions. The scheme has received the support of many eminent authorities, and further particulars can be obtained from the temporary secretary, Mr. L. Blin Desbleds, 39 Victoria Street, Westminster, S.W.

JUST before five o'clock on Thursday morning last, September 23, a fire was discovered in the Technical School buildings, Market Street, Newton Abbot, and although the firemen succeeded in confining the outbreak to one room, much damage was done to the school museum, which included the life-long collection of the late Mr. W. Vicary, of The Priory, Exeter, bequeathed some years ago to his nephew, Mr. W. Vicary, chairman of the governors of the Technical School. The collection was considered to be one of the finest out of London, and many specimens were believed to be unique. It included thousands of specimens of minerals, some being very fine and rare. There were also some fine old flints from Dartmoor, stone implements, and a valuable collection of corals. Specimens from all parts of the world were included in the collection, and many cannot be replaced. There was also an extensive collection of butterflies of numerous varieties, and some magnificent examples of sampler work, some dating from the sixteenth century. The massive cases, valued at about 300*l.*, were completely destroyed, and it is probable that the bulk of the collection is rendered useless by the great heat. Other things lost are the records of the school from 1868, the year of its inception, and a collection of photographs, most of which cannot be replaced, of people who have been connected with the school.

A HOME Grown War Food Exhibition, organised by the *Daily Mail*, was held at the Horticultural Hall, Westminster, last week. When it is considered that the growth, development, and power to function of all the tissues of the body are derived directly from the foodstuffs ingested, there need be no apology for investing these substances with an importance of the first order. To say that the exhibition was a success falls far short of the whole truth It has demonstrated that British people in their thousands (there were more than 20,000 competitors) can produce wheat, vegetables, eggs, butter, cheese, honey, and jams in quality as fine as any other nation in the world. Whether most of these foodstuffs can be produced as cheaply in this country as in France and

Germany remains to be seen. In agriculture, as in art and most departments of human activity, the French do things with singular brilliance and address. Now that we are drawn so closely to France, our agriculturists have excellent opportunities for studying her methods in the various ramifications of their calling. There is evidence to show that the freshness of food plays an important *rôle* in nutrition and problems of health. Since certain vegetables and fruits cannot be imported (even from the Continent) in a thoroughly fresh state, it follows that they should be raised at home. Apart from cost of carriage, there is no reason why we should not produce all our kitchen-garden material, many fruits, eggs, and butter and cheese as cheaply as any nation on the Continent. It requires no argument to-day to establish the contention that the health and physical conditions of the workers in this field are immeasurably better than in any sphere of activity afforded by the city. The only suggestion we have to make relating to the exhibition is that if a label bearing the name of the particular variety of foodstuff were attached to each exhibit, it would afford some valuable information to competitors and visitors. We should now like to see a further exhibition in the form of practical demonstrations of how the various foodstuffs should be cooked.

THE destruction of housefly maggots in manure and other food-stuffs is nowadays a pressing question with sanitary officers. Some recent American experiments are described in Bulletin 245 of the U.S. Department of Agriculture, written by Messrs. F. C. Cook, R. H. Hutchison, and F. M. Scales. Borax and powdered hellebore are found to be the most effectual "larvicides" of all the substances tested.

THE Trustees of the British Museum (Natural History) have published a valuable little pamphlet (Economic Series, No. 2), by Mr. Bruce F. Cummings, on the louse and its relation to disease. The structural distinctions drawn between the head louse and the clothes louse will be of interest to systematic entomologists, while the practical importance of the parasites as carriers of typhus and other diseases is duly emphasised.

THE Food Plants of the Gipsy Moth (*Porthetria dispar*) in America form the subject of Bulletin 250 of the U.S. Department of Agriculture by Mr. F. H. Mosher. From the careful experiments that he describes it has been established that the caterpillars eat, and thrive on, forty or fifty different kinds of trees. It is evident that such discursive feeding-habits make attempts to destroy the insects more difficult.

THE asparagus-beetle (*Crioceris asparagi*) is a well-known pest in Europe and North America. The life-history of its chalcid parasite, *Tetrastichus asparagi*, as lately described by Mr. F. A. Johnston (Journ. Agric. Research, Washington, vol. iv., No. 4), is of remarkable interest. The tiny fly lays usually from five to seven eggs in an egg of the beetle. The beetle's egg nevertheless hatches; the larva becomes fully grown, and, entering the soil, forms a pupal chamber. It never pupates, however, as the chalcid grubs have been feeding and growing within it; they crawl out of the dried cuticle and pupate in the earthen chamber which the host-larva has made.

AN interesting account of the colony of grey seals (*Halichoerus grypus*) of Skerryvore is given in the *Scottish Naturalist* for September by Mr. R. Wilson, of the Skerryvore Lighthouse. This colony, numbering from sixty to eighty, takes up its residence on the outlying rocks every summer, the majority leaving before the winter sets in. Among other things, he refers to their pugnacity towards one another, at any rate so far as the bulls are concerned, and of their curiosity.

THE *Zoologist* for August contains several interesting ornithological papers. Dr. J. M. Dewar discusses the relation of oyster-catchers to their environment from observations made along the Firth of Forth; he finds that the access of the birds to their feeding-grounds in winter is largely dependent on the movements and activities of the human population of the district. The Rev. J. M. McWilliam describes the habits of the tree sparrow in Co. Donegal, mentioning that a couple of males were observed feeding young in one nest, while a lonely female "was sitting on another nest not very far away." Mr. E. Selous continues his "Diary of Ornithological Observations" made in Iceland.

FURTHER notes on the colour sense in bees, from the pen of Mr. C. B. Moffat, appear in the *Irish Naturalist* for September. Mr. Moffat is of opinion that colour is a negligible factor as a means of guiding bees in their search for nectar. They depend rather, he believes, on some subtle sense, perhaps of scent, which enables them to keep to plants of one particular species during each separate journey to the hive. On the return from the hive plants of another species may be visited. Plants of the same species bearing respectively, say, pink and white flowers are visited in succession and at random, but neighbouring plants of different species, bearing flowers of the same hues, are avoided.

EXTENSIVE areas of floating oil off the east coast of Scotland have caused the death of enormous numbers of guillemots, razorbills, and puffins, and a considerable number of eider-ducks. Details as to this extraordinary occurrence appear in the *Scottish Naturalist* for September. Lady Erskine reports that on June 22 at Kingsbarns the rocks were covered with a thick, brown oil, some seven inches deep in the crevices. Dead birds were lying all along high-water mark, and large numbers in a dazed condition, and, with their feathers matted together with oil, were sitting about. Some eiders were also found in a similar pitiable plight. The keeper of the Isle of May lighthouse, on June 16, found birds similarly coated on the rocks, and unable either to fly or swim. Large sheets of oil drifted to the island, and all the creeks on the east side were full of it. The Misses Rintoul and Baxter on June 29 found hundreds of dead guillemots, razorbills, and puffins, and some eiders, on the shore at Cambo. They also report further victims from Largo

Bay and round the shores of Fife. In all these cases the birds were unable either to fly or dive, and hence died of starvation. So far no explanation of this floating oil has come to hand. Probably it escaped from a torpedoed ship bearing a cargo of lubricating oil.

THE current number of the *Quarterly Journal of Microscopical Science* (vol. lxi., part ii.), though considerably diminished in size, contains some very interesting matter. Mr. E. S. Goodrich's article on the chorda tympani and middle ear in reptiles, birds, and mammals should be welcomed by all students of comparative anatomy. In these days of embryological hair-splitting it is refreshing to find that he is able to give a whole-hearted adherence to the much debated theory that the stapes and columella are derived from the hyoid arch, while the incus and malleus correspond to the quadrate and articular respectively. The attention of teachers may be directed to some extremely useful diagrams contained in this memoir, especially text-figure 2, showing the relations of the auditory ossicles and associated structures in reptiles and mammals. Another article in the same number, dealing with the placenta of a lemur, is from the pen of the brilliant Oxford embryologist, Dr. J. W. Jenkinson, whose recent death while fighting in the service of his country is so deeply to be deplored.

W. H. BROWN and D. M. Mathews, in the *Philippine Journal of Science* (vol. ix., Nos. 5 and 6, pp. 413–561), give the results of an elaborate study of the Dipterocarp forests of the Philippine Islands. At low elevations throughout the Indo-Malayan region, the important forests, capable of yielding an extensive supply of timber, are those in which the dominant trees belong to the family Dipterocarpaceæ. Forests of this class occur in the Philippines from sea-level to 2500 ft. elevation, and cover an area of 30,000 square miles. Different types occur, the ecological and silvicultural features of which are well described by the two authors, who give numerous tables of the rates of growth of the main species, and discuss at great length the most suitable methods of utilising the timber, which will ensure successful natural regeneration on the felled areas. Artificial replanting appears to be impracticable. The prevalent opinion that most of the woods of the tropics are very hard and heavy, and consequently only fit for ornamental uses, is not supported by these investigations. On the contrary, it is believed that enormous supplies of soft and light timbers, just as suitable for building purposes as the pine and spruce of northerly regions, will eventually be procured from the tropical Dipterocarp forests, which often consist of dense stands of a few species, that may be logged at a small cost. An export trade in such timber from the Philippine ports has lately been rendered possible by the introduction of cheap American machinery.

THE last issue (1913–14) of the *Bulletin Hydrographique*, published in Copenhagen by the Conseil permanent international pour l'Exploration de la Mer, contains physical observations taken, chiefly in the North Sea, from July, 1913, to June, 1914. The volume includes an admirable series of finely executed maps illustrating salinities and currents, the former in the North Atlantic as well as the North Sea. The current observations are discussed at some length, but the available data are still insufficient to allow laws to be formulated with regard to mean current conditions. Unfortunately, the war has interrupted this international effort, but it is to be hoped it will be continued later. At most stations measurements have been made at 10 metres' depth and near to the bottom, and at fortnightly intervals for three years. The tidal current seems to be least in the Skagerak and the northern central part of the North Sea, greater in the vicinity of the coasts and in the eastern and western parts, and greatest in the southern portion between the Channel and 53° N.

IN *Naturen* for July and August, 1915, C. F. Kolderup discusses and illustrates the Devonian flora of Vestland, between the Nordfjord and the Sognefjord of Norway, on the basis of his researches from 1899 onwards, aided by material in the University collections at Kristiania. The plant-remains confirm the older suggestions as to the age of the sandstones and conglomerates, and the presence of the Orcadian *Thursophyton milleri*, which is probably a Lycopodiale, suggests a Middle Devonian horizon.

DISCUSSIONS of the anemographic observations recorded at Deesa from January, 1879, to December, 1904, and at Karachi from January, 1873, to December, 1894, by W. A. Harwood, are given in vol. xix. of the Memoirs of the Indian Meteorological Department; the discussions are numbered respectively VII. and VIII. There is an introduction by Dr. G. T. Walker, and descriptions are given of the two stations. The year at Deesa is divided into three seasons: the cool season, October to February; the hot season, March to May; and the rainy or south-west monsoon season, from June to September. As each season has its characteristic winds, the data are discussed under the three divisions. At Karachi the year is divided into similar seasons, which embody similar months to the discussion at Deesa. The greatest air movement at Deesa corresponds to the direction of maximum frequency throughout the year. It is north-east in the cool season, and shifts round through west during the hot season to south-west in the rains. At Karachi the predominant movement and the highest velocities are recorded from south-westerly directions at all seasons. The hourly velocities and co-ordinates of wind movement are given for each month for each of the two stations, and there are monthly wind-roses and other diagrams.

WE are glad to see that the war has not interfered with the publication of that very useful periodical, the Journal of the Royal Microscopical Society. In addition to the usual summary of current researches, the August number (part iv., 1915) contains an interesting article by Mr. Charles Singer on the "Dawn of Microscopical Discovery," with reproductions of some microscopical drawings of early date and portraits of some of the pioneers of microscopical science. According to the author, the pioneer period, with which his article exclusively deals, terminated about the year 1660, and was succeeded by the classical period, in

which flourished the great microscopists Hooke, Grew, Malpighi, Leeuwenhoek, and Swammerdam. Amongst the pioneers themselves are included such well-known names as Fabio Colonna, Galileo Galilei, Federigo Cesi, and Athanasius Kircher.

THE June number of *Terrestrial Magnetism and Atmospheric Electricity* contains the results of the measurements of the deviation of the magnetic compass from true north made on the magnetic survey ship *Carnegie* during her voyage from Brooklyn to Honolulu *viâ* the Panama Canal in the spring of this year. The corrections to the British Admiralty Chart are very small over the course from Brooklyn to the West Indies, but in the neighbourhood of the passage between Dominica and Porto Rico the chart gives the westerly deviation more than a degree too small. Across the Caribbean Sea the chart is within a few tenths of a degree of the Carnegie results, but in the first 30° of the course across the Pacific our charts give the easterly deviation about a degree too small. At greater distances from the American coast the error falls to one or two-tenths of a degree, and is sometimes an excess, sometimes a deficit, in the easterly deviation.

IN the Journal of the Franklin Institute for September, Mr. W. S. Bartholomew, president of the Locomotive Stoker Company of Schenectady, says that under average conditions any locomotive, freight or passenger, which has a maximum tractive effort of 50,000 pounds, or burns 4,000 pounds or more of coal per hour for an extended period, one hour or more, should be fired by mechanical stoker. It appears that about 1,200 locomotives in the United States have had mechanical stokers fitted, and about one thousand of these were in use in April last. Some six hundred are Street stokers of the over-feed type, and 365 are Crawford stokers of the under-feed type. It is claimed that the mechanical stoking of locomotives raises the efficiency of the locomotive by increasing the earning power, and also raises the efficiency of labour by making it possible for one crew to handle more traffic per train unit, or the same train unit with greater ease. It also lessens the arduous physical labour of the fireman, and lifts the grade of his employment.

THE *Engineering Magazine* for September contains the first of a useful series of articles by Prof. J. C. Smallwood on recording power plant operations. Descriptions are given of coal meters, feed-water meters, and steam-flow meters; these are thoroughly well illustrated from photographs and working drawings, and contain much information of value to engineers. Coal-weighing apparatus may be classed as registering meters, automatic coal scales, and hand-adjusted weighers. It does not appear that there is any autographic coal meter on the market, although it would appear that such a one would be of distinct use, especially in connection with mechanical stokers. Among water-flow meters, the V-notch weir meter has recently found much favour, as it may be combined with a feed-water heater. Other water-meters described are operated under the Pitot principle, the Venturi principle, and the principle of volume measurement in tanks. Steam-flow meters applied to individual boilers show the instantaneous steaming rate. A meter attached to each boiler of a battery of boilers will show if any boiler is "loafing." The Pitot and Venturi principles are also made use of in steam-flow meters. In the St. John meter the flow takes place through an orifice in which is a conical plug. A difference of pressure of about 2 lb. is maintained. When the flow increases the plug rises, and thus gives an increased area of orifice. A lever system connects the plug to the recording pen.

THE forthcoming books of the *Oxford University Press* include:—The Cures of the Diseased in Remote Regions. Reproduced in facsimile from the original issue of London, 1558, with introduction and notes by C. Singer; Origin and Meaning of some fundamental Earth Structures, by C. P. Berkey; Contributions to the Ethnology of the Salish Tribes, by J. A. Teit; Architectural Acoustics, by W. C. Sabine; Scientific Management, by C. B. Thompson; The Evolution of Modern Medicine, by Sir W. Osler; Geography of Eastern Asia, by D. Paton. *Messrs. Crosby Lockwood and Son* announce, in their "Manuals of Chemical Technology":—Chlorine and Chlorine Products, by Dr. G. Martin, with a chapter on Recent Oxidising Agents, by G. W. Clough; Sulphuric Acid and Sulphur Products, by Dr. G. Martin and J. L. Foucar; The Salt and Alkali Industry, by Dr. G. Martin and S. Smith, with chapters on the Stassfurt Industry and Potassium Salts, by F. Milsom. Further books of science to be issued by the *Cambridge University Press* are:—A Student's Book on Soils and Manures, by Dr. E. J. Russell, illustrated (Cambridge Farm Institute Series); Archæological Excavation, by J. P. Droop (Cambridge Archæological and Ethnological Series); Ticks: a Monograph of the Ixodoidea, part iii., the Genus Hæmaphysalis, Bibliography of the Ixodoidea, ii.; North America during the Eighteenth Century: a Geographical History, by T. Crockett and B. C. Wallis, illustrated; Cambridge Elementary Arithmetics, by J. H. Webster, Teacher's Books V., VI., and VII.; A First Course of Geometry, by Dr. C. Davison; Experimental Physics: a Text-book of Mechanics, Heat, Sound, and Light, by Dr. H. A. Wilson, illustrated (Cambridge Physical Series); An Introduction to Applied Mechanics, by E. S. Andrews, illustrated (The Cambridge Technical Series); Ships, Shipping, and Fishing: with some Account of our Seaports and their Industries, by G. F. Bosworth, illustrated (Cambridge Industrial and Commercial Series).

A CATALOGUE of books and papers on economic zoology and other subjects just issued by Messrs. J. Wheldon and Co., 38 Great Queen Street, W.C., contains the titles of many works of interest to naturalists. We notice that complete sets of reports and other publications difficult to obtain are offered at reasonable prices, and also rare works on fish and fisheries, marine biology, and economic entomology. Librarians and private workers who consult the catalogue will find in it a number of volumes well worth purchasing.

OUR ASTRONOMICAL COLUMN.

A New Comet.—A Copenhagen telegram reports the discovery of another comet by Mr. J. E. Mellish. In addition to the signatures of Profs. Pickering and Strömgren, the message bears the name of Aitken, and the position of the object appears to have been measured at Lick. Thus there are sufficient grounds for presuming an authentic comet has been detected, although the communcation contains no information regarding the movement (or magnitude) of the object. Its position on September 19 16h. 19m. 2s., Lick time, was R.A. 10h. 37m. 54s., dec. 26° 13′ 17″, *i.e.* between 40 and 41 Leo Minoris.

With reference to the note in this column last week, readers who have not the opportunity of consulting Dreyer's Catalogue may be interested to learn that N.G.C. 2261 is therein stated to show a cometic nucleus.

The Variation of Latitude.—Two papers in recent numbers of the *Astronomische Nachrichten* bear on this subject. In No. 4811 Dr. E. Przybyllok publishes results of an investigation into the effect on latitude determinations of that part of the atmospheric refraction due to the air inside the observatory differing in temperature from the external. It is found that measures of the altitude of the pole show a daily fluctuation in magnitude varying directly with the altitude of the sun. Among the numerous citations —there seems to be no reference to the work of Mr. S. Shinjo—one significant item concerns a systematic difference amounting to 0·11″ found between visual and photographic determinations caused by the heating effect of a small dark-room lamp fixed to the south of the photographic zenith sector.

In No. 4812 von B. Wanach discusses the Kimura term "z." Dr. de Sitter's view is adopted that the greater part of this term is due to the method of reduction. Refraction anomalies are considered to be a sufficient cause for the remaining part. The "z" term having been hypothesised out of existence, the attempt is made to modify the group corrections as obtained by the "Kettenmethode," so that in the mean "z" vanishes for all stations and years. To this end a modified "z" is taken as a negative declination correction, and new values are derived for the group corrections for the six northern international stations. The differences between successive groups show an annual oscillation having a maximum in spring and a minimum in autumn, whilst the amplitudes for the three Continental stations markedly exceed those at the "maritime" situations, thus indicating the probability that variations of zenith refraction of meteorological origin are operative.

Stellar Proper Motions determined Stereoscopically.—Quite recently M. Comas Sola, of the Barcelona Observatory, recorded some qualitative observations of stellar cross-motions obtained by stereoscopic comparison of stellar photograms (this col., August 26). According to the *Astronomische Nachrichten* (No. 4811) it now appears that Prof. Max Wolf has employed the stereoscope most successfully in quantitative determinations. Results are given of measures of the proper motions of eight stars in the neighbourhood of σ Leonis made on plates secured with the 16-in. Bruce telescope at an interval of 12·108 years, one of the plates having been taken in 1903, the other in the early part of the present year. The stars measured range from 7·0–12·5m. magnitude, and the yearly motions vary from 0·31″ to 1·18″. Some of the stars have been measured previously, *e.g.* the pair 83 Leonis by Kobold among others, who found the annual motion of 0·77″, whilst the new method gives 0·74″ for the same quantity.

Rotation Period of Neptune.—Mr. Maxwell Hall has published (Monthly Notices R.A.S., vol. lxxv., No. 8) the results of photometric observations of this planet made during its recent opposition; thirty-five measures of magnitude were obtained during the period February 26 and May 10 of the present year. The magnitude ranged from 6·87 to 7·76, and the period which best fitted the measures was 7h. 50m. 68s. Similar observations made during November, 1883, gave a period of 7h. 55m. Greater continuity in the series of observations is necessary, and the co-operation of observers well distributed in longitude is therefore invited.

The Internal Constitution of the Earth.—Mr. Harold Jeffreys, who has recently published several important theoretical investigations on the physics of the earth and moon (Mem. R.A.S., vol. lx., part vi., and Proc. R.A.S., vol. lxxv., No. 8, pp. 648–658), contributes a very useful article to the current number of the *Observatory* on the mechanical properties of the earth. A good idea is given of the manner in which a number of apparently widely differing lines of investigation have in reality converged in adding to our information—albeit at times in a somewhat conflicting fashion—regarding the state of the earth's interior.

Photometric Observations of δ Cephei.—During the period June 10–September 26, 1914, Dr. Giuilo Bemporad and Dr. V. Fontana collaborated in making a fairly numerous series of photometric measures of the light of this star. Dr. Bemporad's results appear in the *Mem. Spett. Ital.*, June, 1915. The mean light curve shows a secondary maximum, and at a later phase an inflection. A further analysis of the data was made with special reference to the secondary oscillations.

The Evolution of the Stars and the Formation of the Earth.—The second course of lectures on the William Ellery Hale foundation was given at the meeting of the National Academy of Science at Chicago last December by Dr. W. W. Campbell under the above title. These lectures are now being published in *The Popular Science Monthly*, beginning in the September number.

THE ETNEAN EARTHQUAKES OF MAY, 1914.

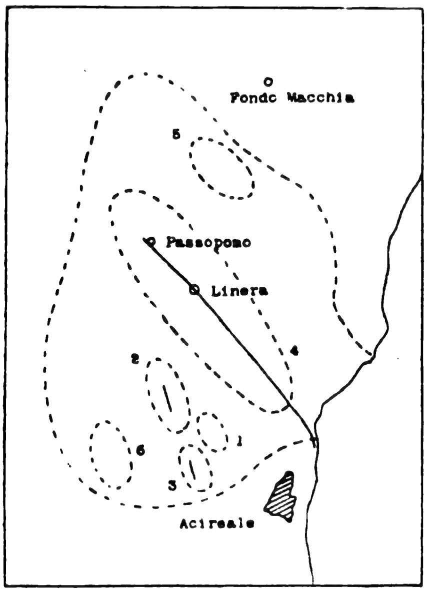
The term *volcanic earthquakes* has for long been applied to all earthquakes originating within the bounds of active or dormant volcanoes. Such earthquakes are usually distinguished from ordinary tectonic earthquakes by their small disturbed areas, the great intensity of the shocks near the centres of those areas, the brevity and abruptness of the shocks, and the comparative absence of fore-shocks and aftershocks. While the countless tremors which precede and accompany volcanic explosions are no doubt the effects of such explosions, it has been assumed, perhaps rather hastily, that all volcanic earthquakes are as intimately connected with the volcanic operations. Several recent investigations (see Nature, vol. xcii., pp. 716–7; vol. xcv., p. 215) have, however, shown that many volcanic earthquakes are of a tectonic or semi-tectonic character, and that both earthquakes and eruptions are in all probability effects of the same cause or causes.

The more important Etnean earthquakes evidently belong to this category. They originate beneath the volcano—in recent cases, below its eastern flank—and they are closely associated in point of time with explosions or periods of increased activity of the volcano. Moreover, their seismic foci are at a slight depth. On

the other hand, the meizoseismal areas are much elongated and their longer axes are directed roughly towards the central crater and at right angles to this direction, implying that they are probably due to slipping along radial and peripheral fractures (see NATURE, vol. xciii., pp. 272–3).

The earthquakes of May, 1914, on the eastern flank of Etna, supply useful evidence on this subject. They have been studied with great care by Prof. Gaetana Platania,[1] who, with ample materials at his command, confirms the conclusion arrived at in the last-mentioned paper. Several of the shocks, besides the principal earthquake of May 8, were of destructive intensity, and the outer broken line on the accompanying map includes all the places in which houses were damaged by the different shocks.

Slight earthquakes were felt within this area on April 28 and 30, and May 1 and 2. The series proper began on May 5. On May 7 at 5.35 p.m. (G.M.T.) there was a strong double shock, the two parts being separated by an interval of three to four seconds. In the epicentral zones, indicated by the curves Nos. 1 and 2, walls were cracked and some houses damaged.



This may, as Prof. Platania suggests, have been a twin-earthquake, but the evidence is insufficient to decide the point. Soon afterwards, at 9 p.m., another strong shock caused slight damage within the area represented by the curve No. 3.

On the morning of May 8, only light vapours were being emitted from the central crater of Etna and from the vent on the north-east flank opened in May, 1911. At about 5.30 p.m., however, extraordinary activity was manifested in both, and this continued for several days with a first maximum on the evening of May 10, and activity above the average for the rest of the month.

Shortly afterwards, at 6h. 1m. 30s. p.m., occurred the principal shock of the series, by which the towns of Passopomo, Linera, Cosentini, Carico, and Mortara were destroyed. The meizoseismal area is an elongated ellipse (No. 4), about 6 km. long and 2 km. wide. There was also a detached area of somewhat less destruction (No. 5). Within the meizoseismal area not only were the houses ruined, but the ground itself was crushed. A slightly sinuous fracture traverses the axis of this zone, as shown by the continuous line in the map, and in its neighbourhood the ruin was complete. Throughout its course there is almost everywhere a change of level, in some places of a few centimetres only, in others of as much as 40 centimetres or more, the ground on the north-east side being depressed relatively to that on the south-west side. There are also traces of a slight horizontal displacement.

Between May 8 and June 4 thirty after-shocks were recorded, only one (that of May 28) being of any importance. The meizoseismal area of this shock is indicated by the curve No. 6. Prof. Platania notes that there were other migrations of the epicentres besides those noted above. He concludes that, during this seismic period, the whole eastern flank of Etna was disturbed, probably by subterranean movements of the magma, which were responsible both for the increased activity of the volcano and for the slips along radial fractures which resulted in the earthquakes.

C. DAVISON.

1 Sul periodo sismico del maggio 1914 nella regione orientale dell' Etna, *Publ. dell' Ist. di Geogr. Fisica e Vulcanologia della R. Università di Catania*, No. 5, 1914. Pp. 1–48.

METEOROLOGY WITHOUT INSTRUMENTS.[1]

THOSE who have been compelled to wade through the long-continued record of meteorological observations know and dread the serried columns of figures that tell of the scrupulous care with which the conscientious observer has read his barometer and thermometer. As a rule, it is impossible to inspire the mechanical and lifeless record of the weather of the past year, or of the past decade, with any lasting interest, but Mr. Backhouse, departing from stereotyped methods, has given us a book on climatology that does not weary by its monotony or tire by its endless repetitions.

Much of the success and charm of this volume depends upon the fact that it is a human document, recording what has been seen and experienced, not what is automatically registered by ingeniously devised instrumental methods. It is a revelation of character as well as an inquiry into the variation of climatic factors. This record goes back to the time when the author was a schoolboy at York, and demonstrates the value of habits of accurate and intelligent observation, diligently preserved through life. With perseverance and practice has come an acuteness of perception that has made Mr. Backhouse one of the most successful observers of those minute differences in the appearance of the sky or of the atmosphere that escape untrained observers, who prefer to consult the barometer rather than natural phenomena. And with the increased capacity for observation has come apparently the greater opportunity for exercising it. To most people, the observation of such phenomena as lunar rainbows or parhelia is a rare event, and without such a trustworthy record as we have here, many would be inclined to doubt their frequency. Take again such instances as the successive alternation in the wind direction, known as "land and sea breezes." Although the cause is operative all over the world, we have come to regard these winds as confined mainly to a few tropical localities, and believe that it would be vain to attempt their observation, except in these favoured spots. But Mr. Backhouse shows how the attentive observer can study the behaviour of these alternating breezes on our own coast, and even mark the varying direction, as the azimuth of the sun, at rising and setting, changes at different

1 Publications of West Hendon House Observatory, Sunderland. No. iv. Meteorological Observations, chiefly at Sunderland. By T. W. Backhouse. Pp. v+188. (Sunderland: Hills and Co., 1915.)

seasons of the year. More important than the record of the facts themselves is the consciousness of how much we miss from failing to cultivate methodical habits of observation.

The manner in which the information is presented and made available adds to the interest attaching to the method of collection. The author sums up his accumulated records, extending over forty years or more, in diagrams, that appeal to the eye. Wind-roses are a familiar device for exhibiting frequent and lawless changes. Similar contrivances are largely used, and demonstrate clearly that the north and east winds grow in frequency as the year advances towards the summer, to be followed later by the increase in the west winds, through the autumn and early winter. The land and sea breezes are similarly treated, and the diagrams are equally instructive. The dependence of rain on wind is also illustrated diagrammatically, and the resulting figures are deserving of close study. The chapter on the prevalence of fog and mist, as determined by the visibility of prominent objects, is of special interest, for it is a kind of observation that cannot be assisted by instruments, but depends solely for its accuracy on the skill and vigilance of the observer, qualities in which Mr. Backhouse excels.

THE BRITISH ASSOCIATION.

SECTION G.

ENGINEERING.

OPENING ADDRESS[1] BY H. S. HELE-SHAW, D.Sc., LL.D., F.R.S., M.INST.C.E., PRESIDENT OF THE SECTION.

THE preparation and delivery of a presidential address is usually a pleasant and not difficult task, although it seems to be the custom mildly to intimate to the contrary. In ordinary times the president chooses a subject on which he has done some work, and with which he is therefore familiar, and with which, moreover, his name is more or less associated. If this had been an ordinary time, I should have liked to deal with the fascinating subject of mechanical locomotion, and to review what has taken place, let us say, since the meeting of the British Association held in Manchester rather more than half a century ago. But the time is not an ordinary one, for the war which a year ago cast its shadow over the meeting of the British Association in Australia has, as the months have passed by, gradually unfolded the most terrible page in the history of the world.

It is terrible not merely because of the frightful slaughter which has taken place and which will yet take place, owing on one hand to the gigantic armies employed, and on the other to the nature of modern warfare. A predecessor in the chair, one who has left many marks of his genius on the peaceful engineering works of the country, Mr. Hawksley, commented about fifty years ago on "the unhappy necessity of devoting so much of the science and skill of members of the association to the defence of the homes of the people of this great nation."

This is not the place to dwell at any length on the subject of the war; but I cannot help pointing out that the whole attitude of scientific and professional men in this country at the beginning of the war shows how little they realised the real nature of what was before us; but we now know that the only way to escape from destruction ourselves is to employ all the resources of science in our own defence.

It is partly on these grounds that the meeting of the British Association for the Advancement of Science has been held this year, because science is proving such an all-important factor in the present war.

The mere holding of this meeting, however, with a vague sort of idea that science is associated with war, does not seem to most of us to meet the real needs of the case. The decision to hold the meeting was made in March, *i.e.* six months ago. Since that time the nation has awakened to the fact that matters have become very much more serious, and we scarcely needed the solemn warnings of our responsible statesmen to enable us to realise this. We see our foe turning every resource towards the active prosecution of the war, and bringing in the aid of every man towards that end. If the result were a small matter, we might pursue our way, as we did at first, with the fatuous cry, "Business as usual"; but day by day it is brought home to us that the Hymn of Hate, childish though it may seem, really represents the serious mind and deadly intention of our enemy. It behoves us all then who are members of it to show that the British Association, which has rendered such great services to the country in the past, can bear its share of the burden to-day.

I assume that we are all agreed upon this point, and it remains to consider the best way in which such a work can be carried out. Understanding from the president that he is dealing with the question from the point of view of the whole association, I need only deal with the matter so far as it concerns our section. After discussing the matter with our secretary and several of my predecessors in the chair, I suggest that we continue the three research committees already in existence, but do not institute a fresh one, forming instead a special committee, the purpose of which I propose to lay before you. Before doing this, I should like to point out that the very fact that engineering constitutes such an important feature of the war has prevented our having, as often in times past, papers on military and naval subjects, such as warships, armour, projectiles, etc. And this for two reasons: first, because nearly every professional or manufacturing engineer having as a rule sent the best of his staff to the fighting line is overwhelmed by actual work either directly or indirectly connected with munitions and war material, and is much better so employed than in talking about the subject, or even in attending the present meeting; secondly, because men who really know all about such work would not be likely to discuss it in public at the present time, and I am sure you will agree with me that we do not want merely popular science on war subjects.

Hence, the twenty-four papers before the section deal with engineering science generally, but I venture to think they are of a high scientific quality, and quite as important in character as those of former years; and, although I need hardly remark that our report on gaseous explosions does not, as suggested by a daily paper, relate to high explosives, it will be noticed in several cases the papers touch closely on subjects bearing on the war, such as those on wireless telegraphy and the traction of artillery.

The object of the proposed committee is twofold. The first of these would be to undertake any work which may be of use in an advisory capacity or by research, or indeed in any other way for direct assistance in the war. This would, of course, be a temporary object of the committee, but nevertheless a real one. I need not go into all that may be done in this direction by the committee, but one step will be to place ourselves at the service of the Ministry of Munitions for such work.

With regard to the second purpose, the matter stands on a rather different footing. We were in many respects quite unprepared for the war on which

[1] Abriged by the author.

we have entered, and though this offers one of the most powerful arguments in refutation of the charge that we deliberately entered the war for sinister purposes, it will be very disastrous if we repeat our unpreparedness when the war ceases, and we shall deserve the worst that can happen to us. When peace is concluded, it will only be a prelude to another war, and a war which will recommence with far greater energy on the part of our enemy than before—viz., the war of commerce—and the latter will be almost as serious for us as the more sanguinary one.

Remembering how soon we forgot that black December week fifteen years ago; and the lurid indication from the German Emperor that he and his people had the will to destroy us then if not the power, and how swiftly we relapsed into national ease at the end of the Boer War, it behoves every man who can do so to take his share in making ready for the terrific struggle Germany is certain to put up in the arts and manufactures. I might give evidence of this from a number of sources, but I will only take one emanating from a body of professors of the great universities of Germany. These gentlemen have published a voluminous manifesto containing, amongst other gems, the following:—"Once the Russians are driven back beyond their new Frontier we shall not forget the war which England has made on the maritime and Colonial commerce of Germany. That must be the guide of our action and we must supplant the world trade of Great Britain. By her blockade of Germany, England has instructed us in the art of being a European Power, militarily, industrially independent of others. We must immediately seek to create for ourselves apart from the Empire of the Seas a Continental commercial enceinte as extensive as possible." It does not, however, want such published evidence to convince any practical person of the folly of thinking that a keen and virile nation having more than 100 million inhabitants is going to be crushed out of fierce and vengeful competition, whatever the end of the war may be. We shall better appreciate what this competition will mean if we consider the progress made by Germany during the last half-century in the arts and manufactures. (The president then gave curves showing the comparative growth of Great Britain and Germany during the last fifty years.)

The above curves are quite sufficient to illustrate the marvellous progress of Germany; and in passing I may remark that one of the most persistent allegations which has been repeated *ad nauseam* by German statesmen, soldiers, professors, and the whole German Press generally, is that the war is caused by our jealousy of this progress. Perhaps you will consider it waste of time even to allude to this matter; but I will take this opportunity of pointing out that if there had been any truth concerning this jealousy, it would have been the simplest thing in the world to shut Germany out of a large number of markets in the British Empire, and that this would have been a very much cheaper process than going to war. Our Colonies, which are now fighting equally with ourselves against German aggression, made a very small difference (5 per cent., for instance, in the case of New South Wales) in regard to the introduction of German manufactures. I myself have somewhat close knowledge of two colonies, and I cannot help recalling the astonishment with which I found in South Africa that, when there was a huge scheme of electrification effected, the enormous amount of material which Germany supplied was for what the public mostly believed to be a purely British enterprise. I also have reason to know that the supply of machinery to New South Wales from Krupp in some cases exceeded by as much as ten times in amount the quantity supplied by British firms. The prices were no higher, in spite of the 5 per cent. advantage to this country. The delivery of the goods was, on one hand, sometimes inordinately delayed, though scrupulously punctual in delivery on the other.

Now, when we look closely into the causes of Germany's great advance, we can learn lessons which we have been culpably slow to take to heart. Although there are other causes, first and foremost, and overshadowing all others, is the determined and whole-hearted organisation of German industry. I see it recently stated that the scheme above referred to (the Victoria Falls scheme) was lost to this country because the industrial banks of Germany backed their own manufacturers, and this is no doubt partly true. As I have already quoted, Germany's power in war is admitted to be her mechanical organisation, and the organisation of every material and engineering force to that end. Just as striking, if not more so, is her organisation for the arts of peace, and I lately heard a very shrewd man of affairs express his amazement at Germany's entrance into war, when by peacefully pursuing the way she was going she would have dominated the world commercially in a few years' time. It is undoubtedly in the matter of scientific organisation even more than the organisation of science that Germany has achieved such wonderful results, and it is therefore in this direction that we must leave no stone unturned if we wish to have any chance of holding our own in the future. I will indicate a few of the matters in which there is ample scope for doing useful work in the above direction.

Education.

A sign of the times is the inclusion of an Education Section in an association for the advancement of science. This has not been done on the narrow ground of improving the teaching of science in schools, but because it is now recognised, and this none too soon, that the whole problem of education must be treated in a scientific manner.

When the subject of engineering education is mentioned we are apt to think only of the training of such engineers as have been considered in a recent report issued by the Institution of Civil Engineers, and to exclude, as that report purposely does, the training of our artisans and foremen. We certainly do not connect the idea at all with the training of the artisan himself. As a matter of fact, while high scientific training of the professional engineer and manufacturer is of vital importance, the proper education of the men whom he will have to control is scarcely less so. The latter education may not be of the same kind, but it is just as vital to the country, and its present condition is a serious evil.

A well-known American, in the *General Electric Review*, writing on the "individual and corporate development of industry," points out that theoretically the aim of both employer and employee is the same, namely, the efficiency of industrial production to increase the return of the investment in labour and in capital. Unfortunately, however, as he remarks, "the relations between the two have frequently been hostile industrial warfare over the distribution of the returns rather than co-operation for the increase of financial returns of both parties."

One of the most humiliating things of the present war has been the mutual relation of the two in this country in what is probably the most critical period in our history. I will say more later on this subject, but there is no doubt the subject of industrial education needs earnest consideration.

(Various matters connected with the education of engineers were then dealt with.)

Research.

If there is one thing more than another which the British Association can be congratulated upon, it is the work which it has done in the matter of research, and it is very interesting to go back to the earliest days, more than eighty years ago, and to see how, in very different days from the present, research in all branches of science was encouraged, and what a potent factor the various meetings have been, not only in actually fostering the work of research itself, but in obtaining the recognition which is accorded it to-day. Amongst other things, the National Physical Laboratory stands largely to its credit, as having been first powerfully advocated at one of its meetings. This section has not been behind the others, and at the present moment there are three research committees, viz., those on gaseous explosions, compound stress, and impact. The work of the first of these is so valuable that its results have been published all over the world.

To-day there is a more general recognition of the importance of research, and the recent institution by the Government of a Committee for the organisation and development of scientific and industrial research is the latest indication that the nation is beginning to realise its importance.

So far from all this making our work less necessary, there is all the more reason why we should have a permanent Committee of Research, because one of the intentions of the new Government Committee is to utilise the most effective institutions and investigators available, and the statement is made that one of the objects of the Government Research Committee is to select and co-ordinate rather than originate, and that one of its chief functions will be the prevention of overlapping between institutions and individuals engaged in research. The Government Committee in question is only dealing with the organisation in England, Wales, Scotland, and Ireland. Now, the great advantage possessed by this association is the fact that it includes not only Great Britain and Ireland, but all the Colonies, and indeed one of the three researches above-mentioned is being carried out in Australia. Another research of the association is being carried out in Cyprus; and work is also being done in such places as Jamaica and Egypt. It is more important therefore than ever that the British Association work in research should go on, as, since its members are drawn from all parts of the British Empire, its influence should be correspondingly great.

(The president then dealt with various aspects of research specially relating to engineering.)

Standardisation and the Metric and Decimal System.

One of the favourite gibes at this country is our supposed utter want of system in regard to our standards and systems of measurement generally. With regard, for instance, to the decimal system, it is frequently stated that thirty or forty countries have adopted the metric system, while only three retain the inch as a standard. It must be remembered, however, that the population and wealth of the three latter are at least equal to, if not greater than, all the others, though this does really not prove anything, except the difficulty of the subject, and that there is a great deal to be said for both sides. In the report of the Decimal Association last April, the hope is expressed that one of the changes for the better arising from the war will be a reform of our weights and measures. No class of the community would be affected more closely than the engineer, and engineers cannot fail to be interested in the question as to whether the general and immediate adoption of the metric system would or would not be a valuable means of assisting British firms in their competition with Germany and Austria, in countries where that system is in vogue. Although it is very unlikely that a wholesale change is imminent, it is certain that the metric system is gradually spreading, and in the United States and Australia very strong forces are on foot to bring about a change to that system. The British Association has over and over again had the subject before it, and our committee might be of service in making a report on the present state of the matter.

One thing is certain: the committee might be of assistance in recommendations which would bring into line all British engineers in duplicating tenders for countries which have the metric system.

Coming to standardisation, here we have more ground for satisfaction. The Engineering Standards Committee during the last ten years has done a work which is quite equal to that in any other country, of completing standardisation of all important matters in engineering, and, moreover, has secured the recognition of these standards in all public contracts.

There is yet work to be done, however, and one matter of great importance would be to get a universal standard of temperature for instruments of measurement other than zero. A temperature, for instance, of about 62° Fahr. would make steel rods' measures more practically workable than at present.

In connection with the subject of temperature and standardisation, I recently came across a statement by the general secretary of the International Electrotechnical Commission (*Journal*, January, 1915) that the want of uniformity in the rating and testing of electrical machinery has been a serious evil, and he goes on to say:—"The German standardisation rules, for instance, which, through well-organised and combined effort on the part of the German makers, had previous to the war become widely recognised on the continent of Europe as well as in many countries to which British machinery is exported, by permitting a higher temperature rise than is considered good technical practice in Great Britain, certainly have not assisted the British maker in foreign markets."

Exhibitions and Museums.

In recent years a large number of commercial exhibitions have been held of all branches of machinery, and it is satisfactory to note that one of the features of such exhibitions has been the holding of scientific lectures, and the inclusion of the exhibition of scientific instruments and apparatus, and also exhibits showing the relation of scientific experiments to engineering work.

(Here follows a number of practical suggestions on this subject.)

Patents and Patent Laws.

This subject is well worthy of the consideration of the proposed committee, since progress in engineering, certainly on the mechanical and electrical sides, is largely dependent upon invention, which is not likely to be seriously undertaken without adequate protection, not entirely for the inventor, but also for those who really make the invention practical by means of capital and business support. A great deal of nonsense is talked and written about inventors, as if they were a special class of being, generally mad and always impossible. Some inventors are both, but the fact is, most engineers spend their lives seeking new ideas and devising new methods of carrying them out, in short, in inventing. It is of the greatest importance that every step should be taken to encourage sound invention and to see that anything of value is secured for this country. Of course, every invention

worth anything is immediately known in other countries, but I need not argue to this section that the country which actually produces the inventions is at a great advantage quite apart from the royalties payable on foreign patents. The foundation of the Munitions Invention Panel is a step in the right direction and will doubtless be followed later on by Government Committees for peace inventions. Such Committees or Government Departments dealing with various industries will be assisted by suggestions from a body like this. Take, for instance, the present state of Colonial patents; within the last few years one Commonwealth patent has been made to cover the whole of Australia, instead of there being, as of old, separate patents with different regulations and fees for each separate Colony. South Africa has not yet conferred a similar boon upon inventors, and we might do something to expedite this desirable innovation. But this touches the much wider question of Colonial Patent Laws as a whole. These are all different and differ from those of the Mother Country. It would be a splendid thing if we could bring about à conference leading to unification of these diverse Patent Laws and have one comprehensive Patent Law for the whole Empire.

A matter in which the German system has certain advantages, is in having two classes of patents. One of these is the patent "proper," which is only granted after the most severe search and criticism and holds the usual period when granted. The other is a secondary patent granted for the shorter term of six years, and is given for one of the hundred and one minor improvements and devices which, though of real value, only constitute small modifications in detail and not new applications of principle.

(The president stated that he believed German patents were fairly granted to foreign applicants, but the common view to the contrary was supported by such statements as in the prospectus of the Deutsche Maschinenfabrik, which runs as follows:—"With the present-day competition every firm is compelled to protect its new designs by means of patents, *and watch that no other patents are granted* which would seriously effect (*sic* affect) it.")

There are other matters, such as the question of giving wider powers to our Comptroller to refuse a grant where novelty is less than microscopic. Here again the German system of demanding that some definite principle is applied *to produce some definitely new effect*, might to some extent be followed, especially in view of the constant accumulation of published devices, some patented and others not.

I will conclude this section, which is far from exhaustive, by pointing out what a debt of gratitude engineers and others owe to the Patent Office for the manner in which the work of producing illustrated abstracts of all patents has been, and is being, done, and the weekly issue of the *Patent Journal*, but this may be associated with the suggestion that it would be a real convenience if, instead of the delay which often occurs, the abstract appeared at the same time or immediately after the publication of the complete specification.

Organisation.

This, I venture to think, is by far the most important question of any I have raised, and I will go so far as to say that I believe it to be the all-important one, as it practically embraces the others. If you do not agree with me, I feel sure it is because we do not understand the same thing by the word "organisation." When you speak of organisation to most people they immediately seize upon some small feature which may be to them of more immediate interest. It may be the general arrangement of their accounts, their system of store-keeping, of dealing with their workmen, of the sales department, of fifty other minor details. If you take this narrow view of organisation you will, of course, at once say that a scientific man has very little to do with it, and indeed the manufacturer as a rule, thinking of his works organisation, scouts the idea that a man of science can either know or have anything to say about it which is of any value.

Let me therefore take the dictionary definition. To organise is to "arrange or constitute interdependent parts, each having a special function, act, office, or relation with respect to the whole." If we accept this definition, which as a matter of fact we must, there is no question as to the all-important nature of organisation, for you will notice there are two outstanding things. The first "interdependent parts"; and the second their "relation to the whole." Thus the subject of organisation really includes the whole of industry. It includes science and its relation to manufacture. It includes the relations between the employers and employee. It includes the workman, and his attitude towards new devices, labour-saving appliances, and output. It includes the whole question of the supply of raw materials, and even the sale and delivery of the finished article. Taking these different features, is there any doubt that the man of science in this country can hold his own, and more than hold his own, with that of any other? The history of invention is quite enough to give a final answer to this question. Again, the British employer and man of affairs has always shown himself individually in the forefront of enterprise; as for the workman himself, he is admitted, in the matter of intelligence, physical endurance, and skill, to have no superior; while with regard to materials for manufacture, and the power of delivering goods, it need scarcely be said that the British Empire, if we take it as a whole, is the richest country in the world in raw materials, and its means of delivery of its good is expressed by the enormous preponderance of its mercantile marine.

When we come, however, to these interdependent parts and their relation to the whole, it is there that we find the weak joint in the armour. It is in this respect that Germany can teach us a striking lesson in the *arrangement* of these interdependent parts with respect to the whole. From the top to the bottom the whole forces of their industries are so thoroughly organised that they get all that is humanly possible out of the various factors. I do not limit this merely to the wonderful organisation of any works, like Krupps, or the Deutsche Maschinenfabrik, or hundreds of other works, but I include the organisation of all the Government Departments, together with the banks, the railways, and the shipping, so that every facility is afforded for the world commerce of the German Empire.

This co-ordination in Germany is carried out in every industry in a way we generally have little idea of. For instance, the other day at a deputation to the Government, Mr. Runciman remarked that the difficulty of connecting the manufacturers with the commercial staffs in this country is deep-seated, but perhaps not altogether incurable. Further, that the manufacturer must realise what he can get from the universities, and the university must know what the works require. Dr. Forster, the treasurer of the Chemical Society, also said that "the Germans were so imbued with the need of pursuing modern and efficient methods of education, in applying science to industry, that they hold in contempt a country which notoriously neglects such processes": and he attributed this contempt as partly contributory to their cheerfulness in entering into the war with us.

Now while these remarks are undoubtedly true, they are only a part of the truth. The evil is far wider than in any special application, for, as the German knows perfectly well, there are innumerable individual cases of organisation in this country of equal efficiency to any in his country, and he is glad enough to learn from special cases. Let us take one, and I do so because it shows that the man of science is capable of industrial and manufacturing organisation, if he turns his mind to it. I refer to the case of the firm known as Barr and Stroud, Ltd. (A brief account is then given of the organisation of the foregoing works for constructing range-finders.)

Now I do not believe the Germans despise us for our want *per se* of the application of science to industry. I do not think they have much reason to; but what they do despise us for is the want of co-ordination, which I venture to say amounts to positive slackness, which they are keen enough to observe permeating the whole of this country. They see different sections, instead of being united for a common end, quarrelling with each other, filled with mutual suspicion and distrust, with apparently no common bond of union, and whereas the German is proud of the Fatherland, he sees in this country large numbers who seem, either through self-consciousness or ignorance, to be ashamed to mention the subject of the British Empire, or, what is worse, to acknowledge that any love of their country is or could be a mainspring and incentive to strenuous effort.

The other day, Field Marshal von Moltke stated, and there is no reason to disbelieve him, that great as was the storage of ammunition and shells before the war, the enormous demand far exceeded all expectation, and Germany found herself for a time in the same plight as her enemies, but he further stated that Germany's emergence "from this dangerous position was largely due to the extraordinary organisation, which included not merely the adaptation of their factories for munition purposes, but *capacity for work of the people,* and the *patriotic spirit of the German workmen.*"

This brings me to consider what is probably the most serious feature in our national life to-day, which I have already alluded to under the heading of education, viz., the relation of employer and workman. It is hopeless, as long as such ideas prevail which seem to do at present, to think of any sound organisation of our industrial system taking place, because the interdependent parts are not arranged (and can never be arranged until we change radically) with respect to the whole. Now as one who has served an apprenticeship, who has taken his money weekly from a tin box with hundreds of other men, who has been a member of the Amalgamated Society of Engineers (in fact, was working as an engine fitter when a Whitworth scholarship made a college career possible), I am the last man to put this evil down entirely to the working man. I know individually he is just as capable of patriotism as any other class. Get him by himself, even the men whose strikes have caused such despondency in the minds of our Allies, and who have seriously jeopardised the very existence of the country, and you will find (except in the sort of case to be found in all classes of society), that he, as an individual, is willing to make sacrifices, and if necessary to give himself for his country. The truth is that the canker which is eating the heart out of our industrial life is due to an entirely wrong attitude of mind. (Various matters illustrating this point were then dealt with.)

The matter of labour disputes is so serious as to demand plain speaking. It must be admitted that there are many employers and companies which, to satisfy themselves and their shareholders, extort the largest possible dividends and pay the smallest possible rate of wages, and do so apparently without the slightest idea that the men and boys under them are capable of education and personal influence. Can it be wondered then that men under these conditions are willing enough to listen to the orator who merely appeals to their fighting instincts and join in the game of grab as against the employer? On the other hand, strikes have occurred when employers have honourably carried out their obligations and undertakings, and the men have shamefully departed from an agreement made by their chosen leaders, throwing over the leaders the moment they have fancied it to their own selfish interests to do so, and without a single thought of their duty to the community as a whole.

We have recently seen the Prime Minister and other leading statesmen struggling, sometimes in vain, to bring large bodies of men to a reasonable state of mind. Is not this (and I speak without the slightest reference to party questions) a case of Nemesis overtaking us for having in so many cases pandered to the selfish instincts of large bodies of men in order to secure their votes, instead of sternly telling them unpalatable truths?

There was recently an intensely interesting article by the late Prof. Friedrich Paulson, previously professor of philosophy in Berlin University, published in the *Educational Review* of New York. In this article, the subject of which was "old- and new-fashioned notions about education," he pointed out that the whole of our educational system was going wrong, and that we could not escape the conviction that a tendency towards weakness and effeminacy was its chief trait. His three mottoes were: learn to obey; learn to apply yourself; learn to repress and overcome desires; and he remarked with great truth under the first heading:—"He who has not learned to do this in childhood will have great difficulty in learning it in later life; he will rarely get beyond the deplorable and unhappy state that vacillates between outward submission and uproarious rebellion."

Is not one of the first things the reform of our educational system?

One of the tasks to which the British Association might bend its energies with the greatest benefit to the country, is to bring about a reform of our educational system, so that while we do not kill individual enterprise and freedom of thought, which have contributed so largely to the political organisation and constitution of the British Empire, of the value of which we have had such wonderful evidence from our Colonies and Dependencies during this war, we seek to implant in the minds of young and old those ideas of discipline and service to the State, the want of which so seriously threatens the successful organisation of our industrial life.

Conclusion.

In bringing my address to a close I hope I have made it clear that I have had throughout a practical object. Expressed briefly, it is that the service of every agency is wanted for definite work at this crisis, both in the actual war, and afterwards in the war of industry which will be waged with equal intensity in peace time. The British Association cannot be said to have undertaken as a whole a work of this kind, yet one finds a general desire on the part of every member that something should be done. With this object I communicated with the president, and found that both he and such of the officers as could be got in touch with were in entire sympathy with the general proposal, and advised that our section, like that of Economics, should start at once with a committee on

the subject. I have great hopes that such a committee will be formed, but I have no hopes of either our own subcommittee or the committee of the association as a whole doing any good, unless they are prepared with definite suggestions and advice which cannot be ignored and put aside. I have not the slightest faith in the mere formation of a committee which will content itself, let us say, with the mere offer of its services, even to a Government department, and the mere pious expression of certain opinions. If a committee does not want to become ridiculous, it must show that it is in earnest. To show that it is in earnest it must take care that its reports have a practical object, can be at once grasped by overworked Ministers and officials, and are of real value.

Fortunately the British Association is a powerful body with great traditions, and will be listened to if such work is carefully and energetically done. We can at least congratulate ourselves that whatever the evils of the war, the country as a whole has been moved from its usual attitude of self-complacency, and that the numerous new departments and organisations are showing a desire to utilise every force and agency for the service of the State, and to grapple with the great problem of its more efficient organisation. It will be no small work of a British Association committee if it can supply sound ideas and recommendations on the many thorny problems which must be solved. We cannot all of us be, as so many would like, in the fighting line, either in France or the Dardanelles, but we shall be just as deserving of contempt as those who have shirked their responsibilities, if we content ourselves with mere offers of service, and having as we think shelved responsibility by leaving initiative to others, we pass along our way sheltering ignobly behind those men and women who are doing their duty to their country.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS [1] BY PROF. CHARLES G. SELIGMAN, M.D., PRESIDENT OF THE SECTION.

IT is impossible to pass to the subject of my address without first referring to the heavy losses which the Teutonic lust of power has inflicted upon our science, no less than upon every other department of humane and beneficent activity. Whatever loss we may yet be called upon to endure there can scarcely be any more regrettable than the death of Joseph Déchelette, whose acknowledged eminence makes any detailed account of his labours superfluous. His valour was no less than his erudition, for though his age exempted him from all military duties, he insisted on taking his place at the head of his old company of Territorials, and was killed last October while leading his men in a charge that carried the line forward 300 yards. We have also to mourn the death of Robert Hertz, a regular contributor to *L'Année Sociologique*, and of Jean Maspero, son of Sir Gaston Maspero, an authority on the Byzantine period and Arabic geography. The other men whose premature death we deplore belong for the most part to that brilliant band of French soldier-explorers to which African ethnography owes so much, and includes Captain René Avelot, whose name will be known to every reader of *L'Anthropologie*.

In my address I shall endeavour to outline the early history of the Anglo-Egyptian Sudan from the point of view of the ethnologist, and thus indicate some of the lines upon which future research may most usefully proceed.

[1] Abridged by the author.

Surprisingly little is yet known of the prehistory of this great area. No implement of river-drift type appears to have been found, and while admitting that this may be due to incomplete exploration, the fact seems of some significance considering the abundance of specimens of this type which have been found on the surface in Egypt, southern Tunisia, and South Africa. With regard to implements of Le Moustier type, I may allude to certain specimens which I have myself collected from two sites, namely, from Beraeis in north-west Kordofan, and from Jebel Gule in Dar Fung. At the former site I found a number of roughly worked unpolished stones. The majority are moderately thin broad flakes, showing a well-marked bulb of percussion, and little or no secondary working; other specimens are shorter and stouter. One surface is flat and unworked, the opposite curved surface shows a number of facets separated by rather prominent crests, all except the central facets sloping more or less steeply to the working edge. In some specimens the crests are sufficiently prominent to give a somewhat fluted aspect to the slope and a crenelated edge, one portion of which often shows signs of having been worn down and retouched. These implements, which I had suspected might have been Aurignacian, were considered by M. Breuil to belong to the Moustierian period, and he referred to the same period and industry some thick, fluted, and engrailed scrapers from Jebel Gule, which I have described as resembling the Palæolithic discs from Suffolk and other localities, as well as some implements of other forms which presented a Palæolithic facies. Besides the disc and Moustierian points, there is one implement which M. Breuil regards as a true, but much worn, *coup-de-poing* of Moustierian age. Whether all these really date from the Moustierian period or not, certain of the specimens from Jebel Gule show a surprising resemblance to South African specimens figured and described by Dr. L. Peringuey as of Aurignacian type, or, in other words, of the Capsien type of Tunisia.

Evidence concerning the later Stone age is furnished by a number of finds made on widely scattered sites; but though no explanation can be offered it should be noted that no stone implement of any kind has been recorded from the Red Sea Province, although it is one of the best known parts of the Sudan, and has been the scene of considerable engineering efforts. This is the more remarkable in view of the geographical features of the country; the absence of forest, the weathered plateaux, the valleys filled with deposits through which innumerable wadis have been cut, all suggest that if stone implements existed some at least should have come to light. Much interest attaches to the distribution of ground-stone axes in the Nile valley. While there is probably no museum with any pretence to an Egyptian collection which has not a number of these, and though they can be bought in almost every curio shop in Cairo, I have been unable to find any record of their discovery in a tomb group or undisturbed burial in Egypt; so that considering the number of prehistoric burials that have been examined, it can be said that they were scarcely if at all known in predynastic Egypt. On the other hand, they are common in Nubia, where a number have been found in predynastic and early dynastic tombs. Many examples have come from Meroë, and I believe that specimens occur on every site of Neolithic date in the Sudan. Moreover, the rock faces on which they were ground have been found both at Jebel Gule and Jebel Geili. We may therefore attribute a southern source to the ground-stone axes of the Nile valley, and in the light of our present knowledge regard them as of Negro origin. This view is sup-

ported by the results of recent work on the prehistory of the Sahara. Gautier, who has devoted much time to the ethnography of the French Sudan, points out, that while at the end of the Neolithic period the northern Sahara had a stone industry characterised by unpolished implements of Egyptian affinities, in the central and southern Sahara the typical implement was the polished axe, and that this was of Sudanese Negro origin. That the boundary of the two provinces, *i.e.* the Berber-Negro frontier, was then some 1000 kilometres further north than it is at present, is in no way opposed to this view. Besides the types already alluded to, Jebel Gule yielded a large number of pygmy implements of quartz, carnelian, and hornstone. These are similar to those found in South Africa and attributed to Bushmen, and there is reason to believe that this industry also existed at Faragab, where the innumerable disc beads of ostrich eggshell were probably bored with more or less worked-up slivers of quartz.

Some mention must be made of the existence of stone monuments of megalithic type in the Sudan, although their number is small and their origin obscure. There is a monolith about two metres high on the plateau overlooking the Khor el Arab near the Sinkat-Erkowit road, to which tradition says Mohammed tied his horse. Another monolith of much the same dimensions has been described and figured by Crowfoot from Isa Derheib, inland from Akik. At present there seems no reason to attribute any great antiquity to these stones; presumably they are connected with the upright stones and "stelai" of Axum. Probably other rude stone monuments will be found in the Red Sea province; indeed, I have heard of such, though the information was never very precise. It is, however, worth noting that typical dolmens do occur in the Madi country in the southern Sudan.

The only rock pictures as yet found in the Sudan are in northern Kordofan. For the most part they are outlined in red or blackish pigment, but a few examples occur chipped on lumps of granite, on the hillside at Jebel Kurkayla in the Jebel Haraza *massif.* These figures are very rough, and the examples reproduced by H. A. MacMichael all represent camels. Drawings with pigmented outlines are found on Jebel Haraza and Jebel Afarit, and from the artistic point of view seem to form two groups. To the first belong rough but spirited sketches of men on horseback, camels, and giraffes. The workmanship of the second group is rougher and much less vigorous; it includes representations of camels, men on horseback, and men marching or dancing, carrying the small round Hamitic shield. This, together with their general resemblance to the "Libyo-Berber" rock pictures of the southern Sahara, indicates a comparatively recent date for these drawings. Moreover, MacMichael notes that the work is faint and indeterminate, and that there is no trace of graving; in other words, the Neolithic tradition has not persisted.

One of the most difficult questions arising in connection with the Sudan is that of ancient Egyptian influence. Its existence may be readily granted, but what of its extent and duration? For while it is a platitude to say that a great and powerful State with a uniform tradition lasting for thousands of years cannot but have influenced the countries on every side, it must be confessed that where history fails the evidence is often extremely difficult to interpret. Every custom which at first sight seems to betoken Egyptian influence must be closely examined, and the evidence carefully sifted, to determine whether it may not have had its origin in the older and more generalised Hamitic culture of northern and eastern Africa. In discussing the value of the data upon which ideas and customs are to be traced back to an Egyptian origin, it is important to remember that general resemblances, either in widely distributed forms of social organisation and belief (*e.g.* matrilineal descent, cult of the dead, etc.), or in widely diffused technical devices (*e.g.* bow and arrow), cannot be admitted as good evidence. Whatever the future may bring, I do not think that in the present state of anthropological science even extreme and unusual beliefs and devices (which at first sight seem so strikingly convincing) should be considered as proof of common influence; otherwise it would be necessary to admit, immediately and without consideration, a cultural relationship between Papua and Central Brazil on the evidence of the phleme-bow, and between England and the Malay States on that of the fire-piston. It is only when there is a considerable consensus of agreement in underlying ideas and (or) in highly specialised customs or devices, that we are justified in considering an Egyptian origin, and even then it is necessary to bear in mind the possibilities of common ethnic origin and of "convergence." It is obvious that under these conditions facts will be differently interpreted, and opinions will vary within wide limits, while new discoveries may at any moment disturb views hitherto regarded as well founded.

Although I propose generally to confine myself to the area included in the Anglo-Egyptian Sudan, yet in considering the question of Egyptian influence in Negro Africa I shall overstep these limits. The records from the Belgian Congo, for example, are more numerous, while recent work in the north-west of Africa has provided material of much value from this comparatively new point of view.

With regard to the mode in which Egyptian influence was exerted on the Sudan there are three main routes along which we might expect to find its traces. The first is southwards along the Nile, the other two are to the west; one route at first following the Mediterranean coast but broadening westward as conditions become more favourable, the other running south-west through the oases and so communicating with Darfur and the Chad basin. Yet another route has been suggested by Sir Harry Johnston, namely, through Abyssinia and Somaliland, presumably reaching them *viâ* the Red Sea. Perhaps it was by this route that the sistrum, still used in the church festivals, reached Abyssinia.

The extension of Egyptian rule up the Nile valley can be traced from the earliest times to the XVIII. dynasty. But although after this Egyptian domination becomes less marked, Egyptian influence had become so firmly established that the culture of the states in the Nile valley had a predominantly Egyptian tinge[2]; first Napata, then Meroë, and then further south the States which we know later as the Christian kingdoms of Dongola and 'Alwah.

On *a priori* gounds the Nile route might be expected to be the most worn and the easiest to trace. For thousands of years Egyptian and Negro were in contact on the middle reaches of the great river, so that at least one great negroid kingdom arose; and though to this day a Negro dialect is spoken as far north as Aswan, yet at the present time there does not seem to be a single object or cultural characteristic which unequivocally can be said to have reached the zone of luxuriant tropical vegetation by way of the Nile valley.

[2] The early Ethiopian kings used the Egyptian language and writing for their records; it was only towards the end of the Meroitic period after the downfall of Egypt, that the Meroitic language was written. A special hieroglyphic alphabet founded on the Egyptian may date back to the third century B.C., but the actual Meroitic script is later than this. Crowfoot indeed argues for so late and short a range as from the middle of the second to the fourth century A.D. (Griffith, "The Meroitic Inscriptions of Shablûl and Karanog," chap. ii.).

The evidence for the earliest spread of Egyptian influence is set forth in the Reports of the Archæological Survey of Nubia. In the reports, Prof. Elliot Smith shows that beyond Aswan, as far south as exploration has proceeded, the basis of the ancient population from the earliest times to the end of the Middle Empire was essentially of proto-Egyptian type, and that this type became progressively modified by dynastic Egyptian influence from the north, and Negro and Negroid influence from the south. As a result, the Nubians contemporary with the New Empire present such pronounced Negroid characteristics as to form a group (the C group) which stands apart from its Nubian and Egyptian predecessors. The recent discoveries made by Prof. Reisner at Kerma in Dongola province show that here was a fort or trading post certainly occupied during the Hyksos period, and probably as far back as the VI. dynasty. It is the remains of the Hyksos period that are especially interesting. Reisner describes a people who razed the buildings of their predecessors, and buried their dead in the débris, who battered the statues of Egyptian kings of the XII. dynasty, and whose funerary customs were entirely un-Egyptian. Each burial pit contains a number of graves in every one of which several bodies had been interred. The chief personage lies on a carved bed; "under his head is a wooden pillow; between his legs a sword or dagger; beside his feet cowhide sandals and an ostrich-feather fan. At his feet is buried a ram, often with ivory knobs on the tips of the horns to prevent goring. Around the bed lie a varying number of bodies, male and female, all contracted on the right side, head east. Among them are the pots and pans, the cosmetic jars, the stools, and other objects. Over the whole burial is spread a great ox-hide." Reisner could not observe any marks of violence, but, judging from the contorted positions of some of the bodies, thought that they had been buried alive. The remains from these burials have been examined by Elliot Smith, who states that the skeletons surrounding the bedstead are those of folk of proto-Egyptian and Middle Nubian (C group) types, while those on the beds belonged to typical New Empire Egyptians, such as lived in the Thebaid at this time.

The first historical capital of the Sudan was Napata, the mediæval Merowe or Merawi, near Jebel Barkal, between the 19th and 20th parallels of latitude, a few miles south of the Fourth Cataract. Napata was certainly an important place in the XVIII. dynasty, but how much earlier is uncertain. In the XX. dynasty the high priest of Ammon assumed the viceregency of Nubia, and there is evidence that during the two succeeding dynasties the priestly families of Thebes set up at Napata a kingdom which, in theory at least, reproduced the theocracy of Ammon at Thebes. The first recorded lord of this new kingdom was Kashta, whose son Piankhi succeeded him about 741 B.C., and by 721 B.C. had conquered and garrisoned Egypt almost as far north as the Fayum. His brother Shabaka founded the XXV. (Nubian) dynasty, which lasted at least fifty years. Thus Napata was Egyptianised, and being a great trading centre cannot but have influenced profoundly the country to the south, so that when Meroe was founded in the eighth century B.C. the ruling influence must have been Egyptian. The mission sent by Nero to explore the Nile reported that Meroe was ruled by a Queen Candace, whose predecessors had borne that name for many generations. Yet, since the monuments show that a king was generally the head of the State, Pliny's assertion requires qualification; moreover, there is the perfectly definite reference to King Ergamenes slaughtering the priests who, as was the custom, had determined his death. In both statements I cannot but see examples of Egyptian theocratic influence. Nor are they mutually destructive if it be remembered that the throne might, and often did, pass in the female line, and that this practice was known to be in full force during the XVIII. and later dynasties. It would be entirely consonant with the policy of the priests of Ammon to take advantage of the spirit of the *sed* festival, the rite of ceremonial Osirification practised by the Egyptian kings, in order to obtain for themselves absolute political control. This would be the easier if among the barbaric tribes in southern Nubia the king was ceremonially killed as he recently was in Fazogli, and as he still is among the Nilotes. Strabo's description makes clear how relatively narrow was the stream of northern civilisation which penetrated Black Africa by way of the Nile valley. But even this civilisation did not come with a steady flow; when Egypt prospered under the early Ptolemies Meroe prospered; as Egypt decayed Meroe fell into the wretched condition recorded by Nero's officers; and even before this Candace could assert that neither the name nor condition of Cæsar was known to her. As northern influence lessened, and the power of Meroe decayed, the black element would preponderate more and more, so that the travellers quoted by Pliny who had actually visited Ethiopia told a story of barbarism and utter stagnation. But even in the earlier and better days when a king exerted real authority at Meroe it would be entirely consonant with African politics and African customs for vassal "kingdoms" to arise at the extremes of the State. So, when it is recorded on the authority of Eratosthenes that in the third century B.C. the Sembritæ who occupied an island south of Meroe were ruled by a "queen" but recognised the suzerainty of Meroe, we may think of the petty chieftains of the eighteenth century who were the true rulers of the country from Dongola to Sennar, though every sultan of Sennar claimed sovereign rights. There may have been many such "states" ruled by women, just as at the present day in the Nuba hills the highest authority passes in the female line, and may be exerted by a woman.

Meroe seems to have been destroyed before the introduction of Christianity. Nevertheless, two if not three culture phases can be traced in its history. There was first a period of Egyptian influence under King Aspelut and his successors, then came an influx of Greek ideas, a phase which Prof. Garstang would date from about the third century B.C. This is the period to which most of the monuments now visible belong, and it was succeeded by the period of Roman dominance. At Soba, on the Blue Nile a few miles above Khartum, Lepsius collected the cartouches of a number of kings and queens of Meroe; this site, the capital of the Christian kingdom of 'Alwah, was certainly inhabited through mediæval times, and may not have been fully deserted till three or four hundred years ago.

No doubt the territory over which the rulers of 'Alwah exerted authority extended south of their capital, yet beyond Soba, in the archæologically unexplored country south of the confluence of the two rivers, traces of northern influence quickly become fewer and less distinct. Nevertheless, at the present day among the hills between the White and Blue Niles the name Soba is still known, being recognised as that of a series of great queens who ruled over a mighty empire of the same name. The Fung or Hameg of Jebel Gule say that the great Queen Soba whom they worship was their ancestress, but they also apply her name to certain rocks which they regard as sacred. A prayer given me by a woman

at one of these rocks ran somewhat as follows: "Grandmother Soba . . . permit us to go on our journey and return in safety." There was obviously the utmost confusion in this woman's mind between Soba the goddess, who may be asked to relieve sickness, and Soba the stone, on which she had just placed a handful of sand. Few will doubt that in the Soba of the Hameg belief there is preserved the memory of such queens as Candace the ruler of the Sembritæ, grafted on the recollection of the great city, which to the Negroids of the Gezira no doubt appeared to dominate the north. Nor do these traces of ancient tradition stand alone; at Jebel Moya near the Blue Nile some 150 miles south of Khartum there is actual archæological evidence of northern influence. Here, besides stone implements, were found beads and amulets, a number of scarabs, and small plaques bearing Ethiopian and Egyptian cartouches ranging from about 700 B.C., or perhaps going back to an even earlier date. I may also note that on the as yet unexplored site of Faragab in northern Kordofan, besides potsherds, stone implements and ivory objects, I have found a carnelian bead, identified by Prof. Petrie as of XVIII. dynasty make, as well as dolomite and scolecite beads which are certainly not of Negro workmanship or character.

These sites seem to mark the southern limit of Egyptian influence as far as the actual transmission of objects derived from the north is concerned. Of the racial affinities of the inhabitants of Faragab nothing is known, but we are better informed concerning the old residents of Jebel Moya. The cemeteries of this site have yielded the remains of a tall coarsely built Negro or Negroid race with extraordinarily massive skulls and jaws. In a general way they appear to resemble the coarser type of Nuba living in South Kordofan at the present day, and it is significant that the cranial indices of the men of Jebel Moya and the Nuba hills agree closely. Thus there is the clearest evidence that Egyptian influence reached south of Khartum, and since it has persisted to the present day in oral tradition among the tribes of the little known country between the Blue and White Niles, traces might equally be expected among the Nilotes of the White Nile. But, strangely enough, nothing of the sort has been found, although the Shilluk and Dinka are better known than any other of the Sudan tribes. On the other hand, the tribes of the Congo basin have a number of customs which do suggest Egyptian influence, and the same may be said perhaps of Uganda, so that it seems reasonable to believe that Egyptian influence spread up the White Nile and passed westwards across the Nile-Congo watershed. An alternate route would be along the Blue Nile and its tributaries, the Dinder and the Rahad, to the Abyssinian hills, southward through the highlands to about 5° N., and thence westward to the head waters of the Congo.

To return to the Shilluk and Dinka, the most northern of the Negro tribes of the White Nile. The fact that no cultural elements which can be connected with Egypt are found on the White Nile, where they might have been expected, suggests either that the tribes now occupying the district were not there when Egyptian influence spread south, or that the country presented such difficulties that the foreign stream left it on one side, as would have been the case had it followed the route *via* the Blue Nile and the highlands of Abyssinia. In other words, either the Shilluk and Dinka reached their present territory in comparatively recent times, or else led a wandering and precarious life in swamps as formidable as the Sudd of the present day. There is, I think, a good deal in favour of the latter view. The existence in the depths of the Sudd of Nuer communities, of which we know little except through rumour, shows that such a life is possible; while among the Dinka the Moin Tain, or "marshmen," who possess no cattle and scarcely cultivate, but live by hunting and fishing, exist under almost as unfavourable conditions. Moreover, there is abundant evidence that North-West Africa is drier now than it was a few thousand years ago, and if those authors are right who state that there was a general melting of glaciers in Eur-Asia some 5000 years B.C., giving rise to widespread floods (the origin of the Biblical deluge), the increased precipitation may well have given rise to a considerable northern extension of the Nile swamps. In support of this argument, it may be noted that in numerous XVIII. dynasty paintings Negroes are represented with bows and arrows and throwing sticks (boomerangs), *i.e.* their weapons are not those of the northern Negroes of the present day, the Shilluk and Dinka, who are not bowmen and do not use the throwing stick. Shilluk traditions state that they came from the south, and a language substantially identical with theirs is spoken by the Acholi of the Uganda Protectorate.

Evidence pointing in the same direction exists on the physical side; the results of the archæological survey of Nubia show that even in late dynastic times the tall Negroids (E-group) whose skeletons have been found near Shellal were mesaticephals, with a cephalic index higher by three or four units than those of the Dinka and Shilluk respectively. On the other hand, a people with a cephalic index nearer that of the northern Nilotes had reached Nubia by the Byzantine-Pagan period (200–600 A.D.). Elliot Smith and Derry speak of these people (the X-group) as prognathous and flat-nosed Negroids who suddenly made their way north into Nubia. Sixteen X-group skulls (eleven male and five female) in the College of Surgeons give a cephalic index of 70·8, and, comparing them with the series of about the same number of Dinka skulls in the collection, my impression is that as a group they show as many Negroid characters.

The numerous records of Negro incursions from the Middle Kingdom onwards suggest that the Negroes were driven north in a succession of waves by some force from which this direction offered the only chance of escape. Such can only have been applied by other Negroes behind them. It may well be that there was more or less continual ferment on the southern border of Egypt in the early part of the first millennium B.C., and that the northern Nilotes were beginning to make their reputation as fighting men. Indeed, the passage in Isaiah can scarcely bear any other meaning than that this people was working north with sufficient energy for their peculiarities and those of their land to have become known to the Mediterranean world. "Ah, the land of the rustling of wings, which is beyond the rivers of Ethiopia: that sendeth ambassadors by the sea, even in vessels of papyrus upon the waters, saying, Go, ye swift messengers, to a nation tall and smooth, to a people terrible from their beginning onward; a nation that meteth out and treadeth down, whose land the rivers divide!" (Isa. xviii. 1, 2, Revised Version). But while the tall Negroes seem to have been the first to reach Nubia in organised groups, stray examples of short brachycephalic Negroes (usually female) have been found as far back as protodynastic times. I am indebted to Prof. Elliot Smith for the information that the four Negresses found in cemetery No. 79 at Gerf Hussein were short in stature with relatively broad oval crania, while at Dabod in a Middle-Kingdom cemetery there was found a skeleton of a

man measuring 1·61 m. (about 5 ft. 3 in.), with definite prognathism, typical Negro hair, and a cephalic index of 80. Presumably these were representatives of the group of short mesaticephalic Negroes who are at the present time found on both sides of the Nile-Congo divide, but predominantly west of it, a group represented by the Bongo, Azande, and cognate tribes. We thus reach the position that the Nubians, who were proto-Egyptians, were, in the earlier part of their history, in contact with just that class of Negroes among whom customs and ideas apparently of Egyptian origin are found at the present day. It must not, however, be assumed that it was this contact that led to the dissemination of Egyptian ideas; indeed, our present information suggests that it can scarcely have been sufficiently intense.

The following table, giving the measurements and indices available for the comparison of the E-group Negroids with the tall Negroes of the present day, shows that the former belonged to the mesaticephalic group, which includes the Burun, the Bari, and the Nuba. As regards head length, head breadth, cephalic index, and stature, the E-group stands closer to the Nuba than to the other tribes, while even in head breadth it is as near the Nuba as the Dinka.

	H.L.	H.B.	C.I.	Stature
Shilluk ...	195	139	71·3	1776
Dinka ...	194	141	72·7	1786
E-group ...	190[3]	143[3]	75·68[3]	1723
Nuba ...	190	145	76·6	1722
Burun ...	190	150	79·16	1759
Bari ...	190	149	78	1741

At the present day the mesaticephalic group includes the Hameg and the Berta of the hills between the White and Blue Niles. The excavations at Jebel Moya—also between these two rivers—have enabled Dr. Derry to show that in Ptolemaic times this hill stronghold was inhabited by tall mesaticephali with a cephalic index almost identical with that of the Nuba, so that we are led to conclude that all these tribes, including the E-group Negroids, belong to one and the same stock.

A number of similarities between ancient Egypt and modern Africa have been set out recently by Prof. Petrie. He does not discuss the routes by which Egyptian influence may have reached Negroland, but simply marshals the evidence of similarity under sixty-one headings. A good many of these are so widely spread outside Africa as to be of little evidential value; others, and this applies specially to material products, include such simple or obvious devices that they can scarcely be regarded as carrying weight; but there are a number of instances which are highly suggestive, and when to these are added yet other habits and customs common to ancient Egypt and Negro Africa, a mass of evidence is presented which seems decisively indicative of Egyptian influence. This view does not imply that all the features common to ancient Egypt and present-day Negroes are instances of borrowing; on the contrary, I hold that many common customs are but expressions of the wide diffusion of old Hamitic blood and ideas. To this ancient stratum I would attribute those customs which I have discussed in a previous paper, including burial by the Nilotes in the crouched position, the use of the throwing-stick (boomerang) by the Beja, and the killing of the divine king (or rainmaker).

The ideas and customs reported from tropical Africa which may be due to Egyptian influence may be classified provisionally in the following groups, though the space at my disposal here permits only a brief reference to the third group:—

(i) Beliefs connected with the soul.

(ii) Beliefs and customs connected with the king or the royal office.

(iii) Death customs.

In Egypt the body was prepared for the grave by an elaborate process of mummification; it was then enclosed in a coffin, often of anthropoid shape. In tropical Africa numerous instances of attempts to preserve the body are recorded. In Uganda the body of the king was opened, the bowels removed, emptied, washed in beer, dried, and then replaced, while among the Banyoro and the Makaraka other methods were adopted. It seems a far cry from the mummies of Egypt to the smoke-dried corpses of Equatoria, and it is not difficult to see that ancestor worship might easily give rise to attempts to preserve the body when everyday experience would suggest desiccation or smoking, but there are certain Congo tribes whose practices do suggest an actual link with Egypt. Among the Wambunda of Stanley Pool the body is placed in the squatting posture, the limbs are tightly flexed on the body and tied in that position, the whole being packed with a large quantity of spongy moss which is kept *in situ* by bandages. A gentle fire is kept up round the body for two or three months, after which it is rolled in native cloths and buried. The latter part of this ceremony hints that the attempts to preserve the corpse may have been imposed on an older habit of speedy burial; such an imposition could only have come from without.

Among the Wangata an important person of either sex is buried in a massive coffin with a lid carved to represent the deceased. It is difficult not to believe that here is an echo of the Egyptian mummy case. If this be so, may not the practice of a tribe near Lake Leopold II., who, after a rough preparation of the body, roll it in native cloth and place it in a canoe-shaped coffin, be regarded as connected with the funerary boats of Egyptian burial ceremony? Since the anthropoid coffin was unknown before the XI. dynasty, it follows that the northern influence must have been exerted after this period. Egypt's first great expansion (after the pyramid builders) dates from the XII. dynasty, when Egyptian and Negro were in intimate contact at the Second Cataract, as shown by the celebrated decree of Senusert III. Further, about this time special importance seems to have been attributed to the funerary voyage on the Nile, indeed, almost all the models of funerary boats in our collections are of this period.

If these facts be accepted as evidence of the date at which Egyptian ideas influenced equatorial Africa, there are other customs which seem to indicate that this was not the only period of such cultural drift. The coffins of the III. and IV. dynasties were often large rectangular boxes designed and painted to represent houses. Now the Mayumbe roll the body of a dead chief in layers of cloth and place it in an enormous wooden coffin of rectangular shape, the top of which is carved to present a homestead. Again, the funeral ceremonial of the Ndolo seems reminiscent of this period. Immediately after death the Ndolo prepare the body, painting it red, touching up the eyebrows with charcoal, and propping it up with open eyes and mouth on a high seat in the very posture of the *ka* statues of the pyramid-builders, *i.e.* seated with the forearms and hands upon the thighs, a position which I venture to say no Negro would adopt. The body remains here for a day, while more or less continual drumming and dancing go on, and is then buried.

[3] The H.L. and H.B. of the E-group skulls have been increased by 7 mm. and 8·5 mm. respectively in order to make these measurements comparable with those on the living. For the same reason the C.I. has been increased by 2 units.

The form of an Egyptian mastaba tomb was to a very great extent the expression of the Egyptian belief that the soul, or souls, of the deceased visited the body in the tomb chamber, coming in and out by the shaft of the pit, and indeed the XVIII. dynasty papyrus of the priest Nebqed represents the human-headed *ba*-soul descending the shaft to visit the mummy. These beliefs also led to the burial of supernumerary stone heads to which the soul might attach itself should the body perish. Recently eight life-size portrait heads of a princess and the courtiers of the court of Chephren have been found in the mastabas at Gizeh constituting the royal cemetery of the fourth dynasty. The cartonnage busts, presumably of the deceased, represented as carried in funeral processions of the Middle Empire, are probably a development of the same idea. Similar expressions of belief—perhaps most obvious in tomb construction—occur in Negro Africa, the examples being too numerous and the resemblances too exact for this to be due to any other cause than actual borrowing.

To sum up: concerning the early prehistory of the Anglo-Egyptian Sudan we have no more than indications. In the Neolithic stage, which appears to have persisted until a comparatively recent date, Negro influence, if not predominant over the whole area, was at least powerfully felt even in the north, as is shown by the distribution of polished axe-heads. But against this northward pressure must be set the continual extension of Egyptian culture, the evidence for which may best be found in the eschatological ideas and burial customs ("mummification" and anthropoid coffins) of the peoples of Equatoria. This influence, which seems to have persisted until medieval times, may have reached tropical Negroland as early as the Middle or even the Old Kingdom. Nor was the Nile route the only one by which Egyptian influence was spread. Another and later drift extended westwards, as shown by the coinage of the north African States, which enables us to fix its date within fairly precise limits. We do not know how far south this drift travelled, but it seems certain that it reached at least as far as the Senegal River and the great bend of the Niger.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—Prof. J. A. Fleming will give a public introductory lecture at University College, on "Science in the War and after the War," on Wednesday, October 6, at 5 p.m. This lecture will be open to the public without fee or ticket. Other free public lectures are as follows:—On October 6, at 2 p.m., Photographic Surveying, by Mr. M. T. M. Ormsby; on October 7, at 2 p.m., The History of Tools, by Prof. W. M. Flinders Petrie, and at 5 p.m., Final Causes in Animal Psychology, by Mr. Carveth Read; on October 8, at 5 p.m., The Physiological Action of Light, by Prof. W. M. Bayliss, and at 5.30 p.m., Steam Turbines, by Mr. W J. Goudie; on October 11, at 3 p.m., Racial Frontiers in Central and South-eastern Europe, by Prof. L. W. Lyde; on October 12, at 5 p.m., An Investigation of the Heating of the House of Commons, by Mr. A. H. Barker; and on October 29, at 5 p.m., The Applications of Electric Heating, by Prof. J. A. Fleming.

The University Officers Training Corps, under the command of Lt.-Col. D. S. Capper, will begin its eighth year of training under exceptional conditions, as the colleges of the University are largely depleted of students. In the infantry unit, the largest in the contingent, the training since the outbreak of the war has been mainly of a continuous character, cadets being accommodated in premises near London. As a rule, a few months of training under these conditions have been sufficient to qualify cadets for commissions. The artillery and engineer units of the contingent are also in active training. Their work is especially important at the present time, as there are so few facilities for the training of technical officers. The artillery unit has been permitted to keep its guns and equipment for training purposes. In the medical schools of the University, a considerable number of students are completing their medical training with a view to taking commissions as soon as qualified. The strength and training of the medical unit of the University O.T C. have therefore not been much affected by the war, and the cadets attended camp as usual. Since the outbreak of war, the number of commissions obtained by cadets and ex-cadets of the contingent up to the end of August, 1915, amounts to 1521, and 189 commissions were obtained before the war, giving a total of 1710. In addition, 245 commissions have been obtained, up to the same date, upon the recommendation of the University, by graduates and students who were not cadets or ex-cadets of the University O.T.C. Before the end of September, the University will have supplied well above 2000 officers to the Army through the O.T.C. or by direct recommendation, and many other graduates and students have obtained commissions through other channels. Distinctions obtained by ex-cadets of the University O.T.C. include:—Military Cross, 6; Medaille Militaire, 1; Mentioned in Dispatches, 14. Under War Office Regulations, membership of the University of London O.T.C. is not restricted to members of the University, and other men of suitable education desirous of qualifying for commissions are accepted Candidates for enrolment should apply personally to the Adjutant at the Headquarters, 46 Russell Square, W.C.

MR. W. CALDWELL, of Trinity College, Dublin, has been elected professor of chemistry and professor of physics in the Schools of Surgery of the Royal College of Surgeons in Ireland.

IN July last the Federation of University Women offered a prize fellowship of 80*l.* to 100*l.* for original work published by women. We learn that the fellowship has been awarded to Miss M. Wheldale, Newnham College, Cambridge.

THE new session of the School of Pharmacy of the Pharmaceutical Society will open on Wednesday, October 6, when the inaugural address will be delivered by Sir Rickman J. Godlee, and the Hanbury gold medal presented by the president.

THE will of the late Mr. George May, mining engineer and colliery proprietor, of Darlington, bequeaths 500*l.* to the North of England Institute of Mining Engineers, the income to be applied in providing "George May" prizes for students, and 500*l.* to Armstrong College, Newcastle, to found a "George May" scholarship in mining.

THE London County Council has arranged for the undermentioned free public lectures to be given at the Horniman Museum, Forest Hill, S.E., at 3.30 p.m. on Saturday afternoons, commencing on October 2: The folk-lore of Russia, Mr. Edward Lovett; the Belgian Congo, its peoples and its animal life, Rev. J. H. Weeks; Rumanian history and folk-lore, Mr. A. R. Wright; (1) our Western Allies, (2) our Eastern Allies, Dr. A. C. Haddon; the folk-lore of France, Mr. E. Lovett; Japanese history and folk-lore, Mr. A. R. Wright; (1) flies as enemies of man, (2) the dangerous parasites of man, Mr. H. N. Milligan; S. Sophia,

Constantinople, and the mosques of Constantinople and Brusa, Prof. F. M. Simpson.

THE calendar of Birkbeck College, London, for the present session has been issued. The arrangements made for the session, which is the ninety-third, are as complete as in previous years. The general character of the educational work provided by the college is summarised in the Final Report of the Royal Commission on University Education in London (1913); the Commissioners write:—"We think that the original purpose of the founder of Birkbeck College and the excellent work that institution has done for the education of evening students who desire a university training, mark it out as the natural seat of the constituent college in the Faculties of Arts and Science for evening and other part-time students." In addition to the university courses arranged in science, arts, laws, and economics, classes will be held in commercial and other subjects.

THE British Fire Prevention Committee's "Fire Warnings" have been before the public from time to time in connection with the war emergency, but the different forms of "Fire Warnings" available and the extent to which they can be obtained gratuitously does not appear to be generally known. Among the "Fire Warnings" obtainable in poster form, printed in red, 8 ins. wide, are the following—the reference number must be given in all communications regarding them:—For elementary and secondary schools: *re* air raids (No. 20); for public schools and boarding schools: *re* air raids (No. 20*a*); *re* fires due to air raids (No. 17): for householders, etc.; *re* fires due to air raids (No. 17*a*): as to dealing with incendiary bombs, etc. Local authorities and school committees —as also headmasters or headmistresses—requiring "Warnings" No. 20 and 20*a* (for schools) will receive a suitable number of copies free upon written application to the registrar, giving the full name and postal address of the institution for which they are required, the number of pupils, subject to their enclosing a large-sized, addressed, and properly stamped envelope for despatching the necessary posters. All communications should be in writing addressed to the Registrar, the British Fire Prevention Committee, 8 Waterloo Place, London, S.W. More than a quarter of a million posters has already been issued by the committee gratuitously.

THE educational and social announcements for the present session at the Northampton Polytechnic Institute, Clerkenwell, London, have been issued in the form of an attractive calendar. The only new evening class which has been arranged is a "Glassworkers'" evening course, which is being jointly undertaken by the technical optics and the technical chemistry departments. The class is required urgently at the present time, owing to the disturbance in this particular trade caused by the war. Notwithstanding the war, the equipment of the various departments was extended during the session 1914–15. In the mechanical engineering department, the testing equipment was increased by the addition of a Heenan and Froude dynamometer, and the prime mover equipment by a semi-Diesel engine. In the electrical engineering department, various transformers and motors of special types were added, and a Tirrell regulator and a mercury arc rectifier were installed. The instrument equipment was also extended. In the technical optics and other departments, a fair amount has also been spent on extensions. The courses in the Engineering Day College are to be continued, but the second- and third-year courses, which extend ordinarily from September to Easter, are in 1915–16 to commence in January and to be continued until July. This arrangement will enable the students to work up to Christmas in the munitions workshop, which has been employed in making gauges and parts of armaments during the whole of the summer vacation. The special classes for Post Office workmen and boy messengers, started two years ago, are being continued, as are also those in submarine cable work for the employees of the cable companies who have their headquarters in London.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 30.—M. Ed. Perrier in the chair.—The president announced the death of Emile Guyou, member of the Academy.—G. **Humbert**: The reduction of Hermite forms in an imaginary quadratic body.—D. **Pompeiu**: A double solution of Riccati's equation.—B. **Mayor**: A correspondence between articulated systems of space and those in a plane.—M. **Gibon**: New methods in stereo-radioscopy. Radioscopic methods are more rapid than radiographic methods, and three processes of stereoradioscopy are described. The first process makes use of two Crookes's tubes, with a metallic diaphragm placed between the bulbs and the patient, a stereoscopic image being formed on a platinocyanide screen.—P. W. Stuart **Menteath**: Some fossils of the Pyrenees.—J. **Pescher**: Respiratory gymnastics and its therapeutic effects. Drawings of the instrument are given, and its use and mode of application are described. Cases are cited in which its systematic employment has given beneficial therapeutical effects. —Edmond **Bordage**: The differences in the appearance of adipose tissue produced by hystolysis in certain Orthoptera.

September 13.—M. Camille Jordan in the chair.—G. **Bigourdan**: Astronomical observations made in France before the foundation of the Academy of Sciences and the Observatory of Paris. An account of the work of early French astronomers up to the sixteenth century.—A. **Chauveau**: Diffuse inflammation of the forearm resulting from a previous general infection.—Paul **Vuillemin**: Essential differences between the nasturtium and the Geraniaceæ. Tropæolum differs fundamentally from the Geraniaceæ in the position of its nectaries and in the typical number of stamens. The author considers it necessary to re-establish the family of Tropælaceæ.—MM. **Tuffier** and **Amar**: Walking-sticks and crutches. Scientific model of a supporting cane. This is designed to prevent forms of paralysis frequently resulting from the use of ordinary crutches.—B. **Galitzine**: The direct measurement of accelerations. A continuation of an earlier paper on the same subject.—A. **Portevin**: The decomposition of potassium cyanate by heat. The reaction $KCN+O=KCNO$ is reversible, potassium cyanide being formed by heating potassium cyanate, in proportions ranging from 20·9 per cent. at 700° C. to 48·9 per cent. at 900° C.—E. Kohn **Abrest**: An arrangement for rapidly testing substances used against poisonous gases. The results obtained with various absorbents for chlorine are tabulated. The solutions containing sodium bicarbonate were not so effective as those with sodium carbonate. Sodium thiosulphate alone gave off SO_2, but in admixture with excess of sodium carbonate the absorptive power was good. Solutions of potassium iodide gave very complete absorption.— Léon **Gizolme**: The influence of the algæ of sand filters on the chemical composition of water. The amount of dissolved oxygen was found to increase and the alkalinity to diminish with increase of sunlight.

Curves are given showing the change in the dissolved oxygen and in the alkalinity with the time of day, and one curve is the exact inverse of the other. These results are attributed to the development of the chlorophyll activity of algæ.—J. **Tissot**: The most favourable conditions for the rapid cicatrisation of wounds. Recent work by Dakin and Carrel aims at the production of a slightly toxic, strongly antiseptic, and non-irritant solution for treating wounds. The author holds that the irritating action of such solutions is essential to their curative action, and shows that various accepted methods of treatment, either physical or chemical, are based on their irritating action. Although the antiseptic properties of alkaline hypochlorites are very high, their favourable action is regarded as being less the result of their bactericidal effects than to their stimulating or irritating effects on the tissues.—M. **Marage**: The treatment of deafness resulting from wounds in war. An account of the results achieved by the application of the methods proposed in an earlier communication. Two-thirds of the cases were able to return to the front as cured.—J. **Rodhain**: The biology of *Stasisia rodhaini*.—E. **Roubaud**: The production and autodestruction of domestic flies by horse manure.

September 20.—M. Ed. Perrier in the chair.—J. **Boussinesq**: Remarks and calculations showing that the complication of the formulæ for large displacements of deformable bodies is due, not to the deformations, but to the rotations.—Wilfrid and Conrad **Kilian**: A reef formation containing stromatospores in the Urgonian of Chamechaude (*massif* of the Grande Chartreuse).—Edouard **Heckel**: The transmission by seeds of the effects of castration in maize stems. It has been shown that one effect of male castration in maize is to increase the amount of sugar in the stems. This has been carried out for four successive years, and it has now been proved that this increased proportion of sugar in the stems can be transmitted by the seeds.—Pierre **Humbert**: The bifurcations of Jacobi's ellipsoids.—C. **Camichel**: Hammering in pipes; oscillations in mass.—Jules **Andrade**: Chronometric methods for the measurement of the terrestrial magnetic field. A magnetised needle is connected with the balance wheel of a non-magnetisable chronometer in such a manner as not to interfere with the equilibrium with respect to the axis of rotation of the balance wheel. The theory of the determination of the magnetic field from the rate of the chronometer is developed, and it is shown that a high accuracy can be obtained.—Jean **Pougnet**: The action of ultraviolet light upon solutions of mercuric chloride and upon some mercury salts. Solutions of mercuric chloride are rapidly decomposed by light from a mercury vapour quartz lamp, calomel being deposited. The reaction is to a certain extent reversible, since calomel suspended in water and submitted to the ultraviolet rays gives some mercuric chloride. Many slats of mercury are also shown to be affected by the same treatment.—R. **Chudeau**: Atmospheric pressure in western and equatorial Africa.—Jean **Mascart**: Description of a localised storm.—B. **Baillaud**: Remarks on the preceding paper.—A. **Moutier**: The troubles of arterial circulation under war conditions. All the subjects returning from the battlefield present a radial hypotension. Other circulatory troubles are frequently observed locally in the neighbourhood of wounds. Treatment having for its aim the regularisation of the arterial circulation will aid conservative surgery and will sometimes remove the necessity for amputations.—A. P. **Dustin**: The method of experimental parthenogenesis of Delage and its mode of application.—A. **Brachet**: The cyclic evolution of the cytoplasm of the fertilised egg.—Mlle. A. **Raphael** and V. **Frasey**: The toxin of the septic vibrion and the corresponding antitoxin. The septic vibrion give in twenty-four hours a very active toxin, which can be easily and rapidly titrated on the rabbit. The immunisation of the horse against the poison can be made rapidly and without danger. The serum thus obtained shows antitoxic and anti-infective properties when used on laboratory animals both against the septic vibrion and *Bacterium chauvoei*.—Em. **Bourquelot** and A. **Aubry**: The biochemical synthesis of the α-monoglucoside of ordinary propylene glycol with the aid of α-glucosidase.

WASHINGTON, D.C.

National Academy of Sciences (Proceedings No. 9, vol. i.).—Alice C. **Fletcher**: The Indian and Nature. Glimpses are given of the line the Indian pursues in his endeavour to express his view of Nature and of the relation he believes to exist between its various forms and forces and himself.—Jacques **Loeb**: The mechanism of antagonistic salt action. The author studies the effect of the concentration C of the salt at the external surface of membranes in addition to the concentrations $C_{,}$ and $C_{,,}$ of the salt outside and inside the membrane, and finds that $C_{,,,}$ is serviceable in explaining the mechanism of antagonistic salt action in certain cases.—Chas. B. **Lipman**: The nitrogen problem in arid soils. A summary of some recent investigations and field manifestations with reference to their bearing on problems of soil fertility in California.—F. H. **Seares**: A notation for use in the discussion of star colours. The extension of absolute scales of photographic and photovisual magnitudes to the fainter stars provides a method of determining the colours of objects at present beyond the reach of spectroscopic investigation, and it is convenient in the statistical discussion of such colour results to introduce a notation similar to that used for spectral classification. The letters *b*, *a*, *f*, *g*, etc., are used to correspond to *B*, *A*, *F*, *G*, etc.—F. H. **Seares** and H. **Shapley**: Condensation, colour, and magnitude in star clusters. Neither N.G.C. 1647 nor M 67 show any dependence of condensation upon colour which cannot be explained on the basis of included background stars; there seems to be little, if any, dependence of condensation upon magnitude, but there is a marked relation between colour and magnitude in N.G.C. 1647, and a less pronounced relation in M 67.—H. S. **Uhler**: Thiele's "phase" in band spectra. The author outlines an interpolation method for determining c in the formula $\lambda=f[(n+c)^2]$, which is much simpler than using Thiele's complicated formula.—E. G. **Conklin**: Why polar bodies do not develop. The second or internal factor in normal fertilisation is a non-diffusible substance which is introduced by the spermatozoon, and it is strongly suggested that this factor is the sperm centrosome, a position which Boveri has long maintained, and which the author has hitherto contested. Giant polar bodies do not develop because they are not fertilised, and they are not fertilised because they are generally formed after a spermatozoon has entered the egg and has rendered it impervious to other spermatozoa.—W. W. **Campbell** and J. H. **Moore**: Radial velocities of the planetary and irregular nebulæ. The fact that the gaseous nebulæ have motions which are characteristic of the stars, and their concentration in the Milky Way, indicate that these nebulæ are members of our stellar system. The great velocities of the nebulæ in the Magellanic Clouds and other considerations lead to the hypothesis that the Magellanic Clouds are isolated cosmic units with no apparent connection to our own stellar system.

CALCUTTA.

Asiatic Society of Bengal, September 1.—Rai **Monmohan Chakravarti** Bahadur: Notes on the geo-

graphy of Orissa in the sixteenth century. The author attempts to discuss in this paper all the geographical information available about Orissa in the sixteenth century. His main authorities are the *Mādalā Pāñji,* or the Chronicles of Jagannatha Temple in Puri (Orissa), and the *Aine-i-Akbari* of Abul Fazal. This information is checked and supplemented by information available at the time of the early British occupation, and obtained by personal inquiries made during his service in Orissa for thirteen years.

PRACTICAL ENGINEERING.

(1) *Plain and Reinforced Concrete Arches.* By Prof. J. Melan. Authorised Translation by Prof. D. B. Steinman. Pp. x+161. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) 8*s.* 6*d.* net.

(2) *Masonry: A Short Text-book on Masonry Construction, including Descriptions of the Materials used, their Preparation and Arrangement in Structures.* By Prof. M. A. Howe. Pp. ix+160. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 6*s.* 6*d.* net.

(3) *Railroad Field Manual for Civil Engineers.* By Prof. W. G. Raymond. Pp. vii+386. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd, 1915.) 12*s.* 6*d.* net.

(4) *Working Data for Irrigation Engineers.* By E. A. Moritz. Pp. xiii+395. (New York: J. Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) 17*s.* net.

(1) "PLAIN and Reinforced Concrete Arches" is an American translation by Dr. Steinman of a German treatise by Prof. J. Melan, who is an authority on structural design, and has invented a well-known system of reinforced arch construction. The treatise is thorough, accurate, and clear. After considering the theory of hinged and hingeless arches, the latter by both analytic and graphic methods, the effects of temperature, displacement of the abutments, and non-vertical loads are examined. Then come arches with elastic abutments, the results being applied to a treatment of arches continuous over several spans, on lofty piers. Reinforced arches are next considered, and there is a valuable chapter on the recalculation of the stresses in an arch ring by a more rigorous method after it has been provisionally designed. The calculations of arches, especially of reinforced arches, are laborious, and fully-worked-out examples of two actual bridges are given, the solutions being in one case by analytic, in the other by graphic, methods. There is a very useful chart for designing concrete sections with double reinforcement.

Prof. Melan has written several books on arched construction, and this one appears to be a condensed but fairly complete statement of the present state of arch theory. In investigating the critical conditions of loading for each arch section, the method of influence lines is used with great advantage. For abbreviating labour in provisional designing, easily applied simple approximate expressions are found. In many cases of double reinforcement the steel bars in compression are understrained. To obviate this, Prof. Melan has invented the method of putting them into an initial condition of thrust by loading them with part of the weight of the centring. The economy obtained is of value, and the method has been adopted abroad, though it is probably little known here. The treatise is very practical, if that can be said of a theoretical treatment of the subject, and can be strongly recommended to any engineer concerned in designing concrete arched bridges.

(2) "Masonry," by Prof. Howe, is an elementary, mainly descriptive account of stone masonry, brickwork, and concrete construction, not including reinforced concrete. Quarrying and manufacturing operations are briefly described, and the different kinds of brick and stone masonry, mass and block concrete, and tools used in different operations. The cement gun is described, used for giving a dense surface finish to mass concrete by blowing a cement grout against the surface.

(3) "The Railroad Field Manual," by Prof. Raymond, consists almost entirely of tables required in surveying and laying out curves. Its peculiarity is that the centesimal in place of the sexagesimal division of angles is adopted. The author remarks that, in practically every railway curve problem, it is necessary at some stage of the solution to transpose from minutes and seconds to decimals of a degree or *vice versâ*, and that it would require much less mental labour to lay out sub-chords if the transit were divided decimally, and, of course, if suitable trigonometrical tables were available. The tables seem to have been carefully arranged and to be accurate. Of course, if the author's method is to be used, the verniers on any transit made as at present would have to be altered to read hundredths of a degree, but this is not a very serious matter. Only experience can prove whether the economy of labour is sufficient to make the change desirable.

(4) "Working Data for Irrigation Engineers" consists in the main (*a*) of hydraulic diagrams and tables giving discharge of canals, pipes, orifices, and weirs; (*b*) of structural diagrams and tables giving earthwork quantities, bending moments on beams, tables for reinforced concrete and timber, etc. Large use is made of graphic diagrams. Some of the information is derived from the records of the U.S. Reclamation Service. The author is competent, and the book will be of service to irrigation engineers.

G

BOTANY AND GARDENING BOOKS.

(1) *Whitby Wild Flowers: A Complete Botanic List of the Flowers, Grasses, and Ferns of the Whitby District (including Levisham and Scarborough), with Notes on their History and Habitats.* By B. Reynolds. Pp. 60. (Whitby: Horne and Son, 1915.) Price 1s.

(2) *Field Book of American Trees and Shrubs: A Concise Description of the Character and Color of Species Common throughout the United States, together with Maps showing their General Distribution.* By F. S. Mathews. Pp. xvii+465. (New York and London: G. P. Putnam's Sons, n.d.) Price 7s. 6d. net.

(3) *Experimental Plant Physiology for Beginners.* By L. E. Cox. Pp. vii+111. (London: Longmans, Green and Co., 1915.) Price 2s. net.

(4) *Elementary Studies in Plant Life.* By Prof. F. E. Fritsch and Dr. E. J. Salisbury. Pp. xv+194. (London: G. Bell and Sons, Ltd., 1915.) Price 2s.

(5) *Climbing Plants.* By W. Watson. Pp. x+132. (London and Edinburgh: T. C. and E. C. Jack, n.d.) 2s. 6d. net.

(6) *Plant Life.* By C. A. Hall. Pp. xi+380. (London: A. and C. Black, Ltd., 1915.) Price 20s. net.

(1) THIS little book gives a useful list of the flowering plants of Whitby and its neighbourhood, including notes on the interesting alien forms which there, as elsewhere on our coasts, are endeavouring, often with success, to become naturalised. It aims also at interesting the holiday visitor in the attractive flora of the district, about half of the book being devoted to excursions in search of wild flowers with the author as pleasantly helpful and gossipy as a leader of such excursions should be. The arrangement of the book is somewhat loose and rambling, and misprints are somewhat numerous and occasionally a little puzzling, such as "Schlerochia" for "Sclerochloa."

(2) The author has packed into this book on American trees and shrubs an astonishing amount of information, with well-arranged and lucid descriptions and a wealth of illustrations both plain and coloured. The appendix contains numerous maps showing the distribution of a large number of species, three or four species being usually shown on each map, together with other useful charts (geological, soil, altitude, etc.). It is much to be wished that a book on similar lines were available dealing with British trees and shrubs, published at an equally moderate price, in such handy form, and with such excellent figures showing details necessary for identification of the species.

(3) This thoroughly practical little book, though limited in scope and dealing only with part of the subject of plant physiology, is about the best of its kind that we have seen. The directions for experimental work with simple materials and apparatus more than make up in clearness what they lack in novelty, and the beginner who works through the experiments will certainly have nothing to unlearn on proceeding to a more extended study of plant physiology. It seems a pity that some work on movement in plants, other than tropisms, was not included; even the beginner for whom the book is intended ought to know from experiment that plants can perform movements of greater agility than those involved in growth responses to such factors as gravity and one-sided illumination.

(4) This little book is apparently in the main a condensed and simplified version of the same authors' "Elementary Studies in Plant Life," and it presents the same excellent features—clearness of description, abundance of good illustrations, and a just appreciation of the importance of physiology and ecology in the study of the elements of botany. It would not be easy to find a book better suited to the needs of junior students.

(5) The name of Mr. William Watson on the title-page of a gardening book is a sufficient guarantee of the accuracy of its contents, and this handy volume on climbing plants is a most welcome addition to gardening literature. The claims and possibilities of climbers are admirably dealt with by Mr. W. Robinson in a wise and witty introduction, and the book certainly ought to stimulate interest in the culture of this somewhat neglected class of plants. No fewer than one hundred genera, many of them with several species, are dealt with by Mr. Watson in his usual precise and helpful manner; valuable hints are given as to the selection and cultivation of hardy, greenhouse, pergola, tree, and other climbers; the systematic notes are arranged in alphabetical order under the genera; and there are twenty-four excellent plates, eight of them coloured. These beautiful and wonderfully cheap "Present-day Gardening" volumes are worthy of a more durable kind of binding; few would grudge paying a little more if necessary in order to have something more substantial than the cardboard backs, which get badly rubbed and cracked in a short time even with careful use.

(6) The author's attempt at the compilation of a "popular botany" is somewhat more ambitious than usual in the case of such works, and certainly more successful so far as accuracy is concerned. We have little doubt that those who can

afford to buy a somewhat expensive book, and probably many will be willing to lay out twenty shillings on a handsome volume with fifty fine coloured plates, will agree that it serves admirably the twofold object of its existence, namely, usefulness to the amateur botanist and an easy introduction to the study of more technical works. The author has evidently selected from a tolerably good modern botanical text-book such parts as are amenable to popularisation and has presented the facts in a simple style, somewhat marred by an extensive use of unnecessary tags and phrases.

It would be easy to criticise various portions, but bearing in mind the difficulty of writing a thoroughly satisfactory book of this kind and the unpretentious objects aimed at by the author, it may be enough to say that it is one of the most attractive books of the kind we have seen. The coloured plates, from drawings by Mr. C. F. Newall, are remarkably fine, being accurate alike in colouring and in structural detail, but we should have liked to see a larger proportion of them devoted to the flowerless plants, especially as the considerable portion of the text dealing with these constitutes one of the best features of the book. The concluding chapter, dealing with ecology, is rather feeble, and will, we fear, give the uninformed reader a somewhat inadequate idea of the methods used and results obtained in this branch of botanical study; but we have not yet seen anything approaching a satisfactory "popular" account of what writers of books of this kind appear to have agreed to designate "the new botany," though as understood by them it is certainly neither new nor interesting, but merely a hotch-potch of "wonderful adaptations," or of obvious remarks about different kinds of plants growing in different kinds of positions, the reader being supposed to infer that until quite recently nobody ever noticed such astonishing facts as that moorland plants do not grow in salt marshes and *vice versâ*!

NEW METHODS AND OLD.

(1) *A Campaign Against Consumption: A Collection of Papers Relating to Tuberculosis.* By Dr. A. Ransome. Pp. viii+263. (Cambridge: At the University Press, 1915.) Price 10*s.* 6*d.* net.

(2) *A Chaplet of Herbs.* By F. Hine. Pp. xv+168. (London: G. Routledge and Sons, Ltd., n.d.) Price 2*s.* 6*d.* net.

(1) THE author, whose work relating to tuberculosis is well known, has done well to bring together the various papers he has contributed on the subject. The book is divided into four sections. The first, of a general character, deals with consumption, its causes and prevention, and the duties of the State in regard to tuberculosis. The second section discusses the conditions of infection in tuberculosis. Section iii. gives a summary of the author's researches on tuberculosis, such as treatment of pulmonary disease by means of intrapulmonary injections, media for the cultivation of the tubercle bacillus, etc. The last section is mainly statistical, and discusses such subjects as "The Public-house as a Source of Phthisis," "The Prospect of Abolishing Tuberculosis," and "Phthisis Rates."

Dr. Ransome considers that there is a fair prospect of abolishing tuberculosis, considering that the disease is steadily declining, which must be attributed to an inherent weakness of the microbe at the present time, and that we now possess potent weapons with which, when fully put into action, we may fairly hope to accomplish the final conquest of the foe. The author was optimistic enough in 1899 to suggest that another thirty years should see its vanishing point!

Altogether, much valuable matter has been brought together in this volume.

(2) This little volume of extracts is calculated to give leisure moments of real delight. The author has collected them from old herbals ranging from the eighth to the eighteenth century, and more particularly from those of the golden age of herbalists, 1450–1650. She has shown in her choice of extracts a sympathy and a humorous appreciation which are very attractive; a vein of laughter and delight runs through the book, with kindly charity and gentle raillery for the light-hearted, inconsequent old herbalist. In the introduction is an appreciation of the genuineness, and withal, the quackery, of the herbalists, their weakness for a far-fetched recipe, and their child-like trust in Mother-Earth, dear Dame-Nature.

Here are some extracts:—

"If anyone has over-eat himself, or drank too much; as feasts and pleasing company will lead the wisest into this mistake sometimes, Polypody is the best remedy. . . ."

"To make a woman shall not eat of anything yt is set on the table. . . . Take a little green Basil, and when ye dishes are brought to ye table put it underneath them. . . ."

Remedies for the green sickness and for "Chincough" (hiccough) are enlightening, and involve a pleasant use of alcohol; while thyme helps agues, hickup, lethargy, frensie, megrim, colick, convulsions, melancholy, and resists poison.

We have reason to be grateful for the names of flowers alone, cowslip or paigles, chickweed

or gromel, and flag, gladen, or water-segg for the wild iris.

There is throughout the book a sense of pungent fragrance as of a bunch of herbs, and the "chaplet" is, as the quoted foreword claims, indeed "not short in savour."

R. & L. H.

OUR BOOKSHELF.

The Analysis of Non-Ferrous Alloys. By F. Ibbotson and L. Aitchison. Pp. vii+230. (London: Longmans, Green and Co., 1915.) Price 7*s.* 6*d.* net.

AT such a time as this, when there is a large demand for metals and metallic alloys of all descriptions, it is of the greatest importance that the manufacturers and users of these materials should have at their disposal rapid and accurate means of controlling the chemical composition of the goods they handle.

Until comparatively recently the "commercial" chemical analysis of non-ferrous alloys has received but little attention, at any rate from those most concerned, so that one has been forced to go for one's information to a series of widely scattered original papers in the various scientific and technical journals. A text-book embodying all the best of the information at present available is therefore exceedingly welcome.

The work under review may be divided broadly into three parts. The first part enters into a detailed description of the most recently devised apparatus for electrolytic analysis, and discusses the main theoretical considerations underlying the successful deposition of the metals.

The second part reviews the action of sulphuretted hydrogen on solutions of the metals under varied conditions of acidity, temperature, concentration, and time. Then follows an exhaustive description of the best methods for the estimation of the various metals in solutions of their salts.

The remainder of the book is devoted to the application of the foregoing methods to the analysis of brasses, bronzes, "white metals," and other alloys of industrial importance.

The value of the book is enhanced by a very complete bibliography. The book should prove of great value to works chemists and to the more advanced students in technical schools.

B. W. DRINKWATER.

Science of Dairying: a Text-book for the use of Secondary and Technical Schools. By W. A. G. Penlington. Pp. viii+260. (London: Macmillan and Co., Ltd., 1915.) Price 2*s.* 6*d.*

THIS volume covers a very wide range, and is intended to be used as a text-book of dairying in secondary and technical schools. It deals first with the composition and properties of milk, and gives particulars of the methods employed in the detection of adulteration. Two chapters are devoted to bacteria and the important part they play in dairying. A later chapter gives working details of the two best known rapid methods for the estimation of fat in milk. The first of these—the Babcock test—is not employed commercially in Great Britain, but is common in Australia, New Zealand, and Canada, whereas the second test—the Gerber—is universally practised in this country.

The principles, and outlines of the practice, of butter- and cheese-making are given in a clear and concise manner. The author then passes on to consider the physiology, feeding, care, etc., of the cow, and some of the common diseases to which she is subject. A chapter deals with arithmetical problems arising in dairy practice.

The book is written apparently for those who take up dairying more as a subject of examination than as an end in itself, and it is a little difficult to see to what class of English readers it will especially appeal. Without question, the educational value of such a work is considerable, but as dairying as a subject is not generally taught in the secondary schools in this country, the demand would appear to be limited to those attending a county dairy school, particularly those who are not following a systematic course of training. In the latter case the details are insufficient, but as introductory to the subject all students—whether short or long course—would benefit by a study of the book.

The Internal Combustion Engine: a Text-book for the Use of Students and Engineers. By H. E. Wimperis. New and revised edition. Pp. xvi+319. (London: Constable and Co., Ltd., 1915.) 6*s.* 6*d.* net.

SINCE the first edition of this book was published in 1908, there have been many important developments, both scientific and practical, in the internal combustion engine. These developments have necessitated many changes and additions in the present volume. The book is divided into three sections, the first of which treats of the theory of the subject. After describing the more elementary theorems in thermodynamics and the cycles employed, the author gives a very good account of the numerous experiments which have been made on explosions in closed vessels, and on temperatures inside the working cylinder. The second section deals with gas engines and gas producers, and includes information regarding the Humphrey gas pump, gas turbines, and Hopkinson's water-injection system. Methods of testing and of reducing test results are also given. The third section deals with oil and petrol engines and contains a good discussion on the Diesel engine, and on petrol engines for motor-cars and aircraft.

The illustrations are very good and clear. At the end of each chapter is given a number of excellent exercises, many of which have been taken from recent Cambridge examination papers. The book is very well adapted for the use of students, and has the merits of being moderate both in size and price.

Elementary Photo-micrography. By W. Bagshaw. Third edition. Pp. 143. (London: Iliffe and Sons, Ltd., 1915.) Price 2s. 6d. net.

SOME idea of the scope of this volume may be gathered from the fact that about ninety of its pages, which are not very large, are devoted more especially to photo-micrography, and rather more than thirty to photography—that is, developing and printing. The author takes it for "granted that the reader is already familiar with the use of the microscope," and also presumably that he is an amateur photographer, and seeks to show how the two may be brought together without the need for expensive appliances, and furnish results which, "though not perfect, are good and acceptable for nearly all purposes." He succeeds not only by precept but also by example, giving twenty-nine good reproductions of photo-micrographs taken by the simple means that he describes, using only objectives supplied with students' microscopes. These examples are illustrative of the methods dealt with in the text, and include magnifications from 2 up to 4000 diameters, the use of transmitted light, reflected light, a combination of the two, dark ground illumination, the use of polarised light, oblique illumination, illumination by flashlight, multiple-colour illumination, and a photograph on an autochrome plate. They are of excellent quality, including even a photograph of *Bacillus subtilis*, ×1000. But the *Amphipleura pellucida*, ×4000, shows that such simple methods will not serve for an extreme test, although taken by means of a one-twelfth immersion lens of 1·4 N.A. and an oiled-on condenser. By the way, such an objective and condenser scarcely come within the range of "students'" microscopical apparatus. In giving "pre-war" prices for chemicals, perhaps the author expresses his faith in an early return to peace conditions.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Masses of Heavenly Bodies and the Newtonian Constant.

IN a well-known treatise on physics we find the following statement:—"By the third law of Kepler we are led to the conclusion that the same value of G (the Newtonian constant of gravitation) applies to the sun and all planetary bodies." This conclusion appears to be fallacious, as we see by the following elementary considerations:—

(1) Take the case of Poynting's famous balance experiment for determining G. The attraction of the large mass M on the small mass m at distance d is

$$\text{couple} = G_M . Mma/d^2 = m'gl' \quad . \quad . \quad . \quad (1)$$

where m', l' are the mass of the balancing rider and its displacement necessary to counterpoise the gravitative pull of M on m.

Equation (1) gives G_M, for we know all the other factors. The suffix used here denotes that the "constant" G_M only applies to a mass if its temperature is that of M.

(2) The earth's attraction on mass m is

$$mg = G_E . Em/R^2. \quad . \quad . \quad . \quad . \quad (2)$$

where E, R are earth's mass and radius respectively.

Equation (2) gives us $G_E . E$. The earth's mean temperature may be, say, 4000° C., whereas that of M above is, say, 15° C. We have no experimental knowledge that the Newtonian "constant" is the same at 15° as at 4000°. Hence we cannot write $G_M = G_E$ and obtain from equation (2) the earth's mass. It is thus evident that the values commonly given for earth's mass and mean density are based on the unwarrantable assumption that $G_M = G_E$. Thus it is quite possible (for we have no evidence to the contrary) that $G_E = 2G_M$, in which case the earth's mean density would work out to be 2·76 instead of 5·52, as generally accepted.

(3) When we come to the case of the revolution of the earth and other planets round the sun, we have similar considerations to the above. Let two planets have mean radial distances d_1, d_2 and periodic times t_1, t_2, we obtain in the form of Kepler's third law

$$G_S . S = 4\pi^2(d_1^3/t_1^2) = 4\pi^2(d_2^3/t_2^2) = 4\pi^2 k,$$

where S = sun's mass and G_S the Newtonian constant for the sun's temperature, whence we obtain $G_S . S$; as we know Kepler's constant k. We do not know S alone, for we may not write $G_S = G_E = G_M$.

Thus we see that the masses and densities of all heavenly bodies, including the earth, are based on an assumption for which there is no experimental support, and which (considering the great range of temperature involved) is probably false.

In the case of the sun, the stars, and all the major planets the mean temperature is certainly as high as four figures, and in many cases probably five figures, on the Centigrade scale. It is thus inconceivable that any laboratory experiment will ever be made to determine the values G_S, G_P, or even G_E. But it is not unlikely that sure experimental evidence will be forthcoming as to the value of G, say, up to 500° C.

I have recently concluded a long research on the value of G up to 250° C., and I have found an increase in that "constant" of about 1 in 10^5 per 1° C. The full results I hope to publish shortly.

No doubt it has been for the sake of simplicity that astronomers and physicists have assumed constancy in G, and have thus obtained the accepted values for mass and density. But in reality these values (by analogy with the terminology of radiation) are not the mass and density, but the *effective-mass* and the *effective-density* respectively, and would only be true-mass and true-density if $G_S = G_E = G_M$, etc. If any temperature effect, such as is mentioned above, can be firmly established, then these terms ought to be adopted in the interests of accuracy.

So far, for simplicity, we have considered the temperature effect of gravity on the large mass only and have ignored any effect on the small mass. In equations (1) and (2) we have the small mass m at ordinary temperatures, say 15° C., so that we have not to consider temperature effect in connection with it. But in equation (3) the two planets in question may differ in temperature. Even then the equation is correct as it stands, supposing (*a*) the temperature effect on a mass considered as one member of a gravitative couple is identical with (*b*) its effect on mass considered as so much inertia; for these terms (*a*) and (*b*) occur on the left and right sides of the equation and cut out. But, on the other hand, if (*a*) is not identical with (*b*) the equation would have other factors. But neither in this

case nor in the other can the equation (3) be made to prove the quoted statement with which this article begins.

Although the above considerations are theoretically of profound importance, they will obviously have no influence whatever on astronomical calculations; for in all such calculations the product of mass into Newtonian constant is used. Suppose in the case of the sun $G_S > G_M$ and let S, S′ be the true sun's mass and its present accepted value, then

$$G_S . S = G_M . S'.$$

In no calculation do we require S alone, but always product $G_S . S$, so that the false values for the sun of G_S and S do not lead to error.

P. E. SHAW.

University College, Nottingham.

The Spectrum of X-Rays.

(1) KOSSEL (*Verh. d. D. Phys. Ges.*, 1914), discussing the previous measurements of the frequencies of the corresponding lines of the spectrum K and L characteristic for different elements, as well as of the limits of the respective bands of absorption, established certain numerical relations among them which Wagner (*Ann. der Physik*, 1915) confirmed in a more perfect way and even generalised. In addition, the extremely precise measures of Bragg and Pierce (*Phil. Mag.*, October, 1914) for the lines K_α, K_β, K_γ in the Ag, the Pd, and the Rh give additional confirmation.

From among these relations, attention is specially directed to the one obtained by generalising the second law of Kossel—

$$L_\alpha = K_\beta - K_\alpha, \text{ viz., } (1)\ M_\alpha = L_\gamma - L_\alpha$$

In these equations each term expresses the frequency of the lines. With its help we can foresee the frequencies of the principal lines of the spectrum of the M characteristic if L_γ and L_α are known.

If we admit Bohr's model for the atom as modified by Kossel—that is to say, supposing that in the transit of an electron from one ring to another a quantum is emitted, the frequency of which is determined by Bohr's formula, the radiation M will correspond to the transit of an electron from the fourth to the third ring, and the corresponding frequency,

$$\nu = \nu_0\left(\frac{1}{3^2} - \frac{1}{4^2}\right)\left(N - a\right)^2 = 1.59 \times 10^{14}(N - a)^2$$

will be emitted.

To demonstrate the exactness of this prediction, I have calculated the values of ν contained in the following table by means of the formula (1), starting from the values of L_α and L_γ given by Moseley, Rutherford, and Andrade. The last row contains the values of ν obtained from the formula—

$$(2)\ \nu = 1.39 \times 10^{14}(N - 21.8)^2$$

deduced by graphic interpolation, where N is the atomic number of the element.

	N	ν cal. by (1)	ν cal. by (2)
Pd	46	81×10^{15}	82×10^{15}
Ce	58	189	182
Eu	63	245	236
Ta	73	364	365
Pt	78	438	440
Au	79	452	455
Radium B ...	82	501	505

As can be seen, the formula (2), of similar type to those found by Moseley for K_α and L_α, shows well enough the change of M_α with N, and besides the constant $1{\cdot}39 \times 10^{14}$ coincides with the theoretical value $1{\cdot}59 \times 10^{14}$, between the limits to be expected on account of the method of calculation. No data are at present available to test this hypothesis. The spectrum M is most likely to be observed in heavy elements and in the radio-active bodies.

(2) In the numerical relations obtained by Kossel and Wagner, there does not appear the groups L_{α_2}, L_β, and L_δ of the spectrum L, nor does there seem any simple way of introducing them in another series of formula involving the frequency of the K radiations. This suggests the possibility of the spectrum being composed of two distinct parts, which might be illustrated by supposing that two rings are situated in distinct planes, from one of which (the one corresponding to L_2) no electron can pass to the ring K. The correctness of this hypothesis could be tested by investigating experimentally the lines of the L spectrum that accompany the spectrum K—a study that does not seem impossible.

It is logical to suppose that this group L_2 should be accompanied by others, M_2, N_2, . . . in the exterior spectrum, and even that in these should appear some new ones—M_3, N_3 . . . N_4 . . . In this way it would be easy to understand how the spectrum gets more and more complicated from the X-ray spectrum to the visible, and even the existence of the well-known series in the light spectrum.

Studies of the Cotton Plant.

I SHOULD be sorry if any reader of NATURE were to be prejudiced against perusal of my book on applied plant physiology, called "The Development and Properties of Raw Cotton," by thinking that I had attempted to write on the systematic botany of Gossypium. Yet this impression might easily obtain, since your reviewer devotes exactly two-thirds of his review to a few pages of my first chapter, the title of which, "The Development of Pedigree," is alone sufficient to indicate that it was not intended for biologists.

Still, technological treatment is no excuse for inaccuracy, even as enthusiasm for herbaria is no excuse for such a phrase as "peripatetic Mendelian cross-breeding of undetermined stocks." Therefore I would direct your reviewer's attention to the fact that my description of Gossypiæ as a sub-order (instead of a tribe) is taken from an accepted authority on systematy.

He states that "the results and evidences of systematic botany" with regard to cotton have been before us for a long while; the Hindi weed-cotton to which he purposely refers is a sad example of the result. I regret being obliged to mention it, but he misspells it as "Hindu" weed, and then objects strongly to my leaving it with such a loose designation. Now, in the first place, this name is on record in Sir George Watt's standard monograph of the genus, and is therefore as definite as any other. Possibly more definite, for though the specimen used for that determination came from a pure strain, Sir G. Watt called it "a ferine hybrid possessed of a strain of *G. vitifolium*." Only by enlisting the aid of "peripatetic" Mendelism can one justify the apparent contradiction, but nothing *a priori* can excuse the inclusion of this Hindi weed in the "fuzzy-seeded cottons" during the primary division of the genus in that monograph. There is no cotton which has a more naked seed than Hindi.

It is clear that I took too much upon myself in attempting to persuade the growers and spinners of

cotton—in the first dozen pages of the book—that the systematic botany of cotton had some definite meaning. Nor did I think that any reviewer would be so ruthless as to drag my little jest (about scientific names appearing to be "merely useless duplicates of easier names") out of its context to pelt me.

W. LAWRENCE BALLS.

Little Shelford, Cambridge, September 16.

MR. LAWRENCE BALLS's objections to my review of his book, "The Development and Properties of Raw Cotton," which appeared in NATURE of August 26, call for a reply from me.

I feel quite sure Mr. Balls need have no fear that my remarks will be viewed, by even the most casual reader, as the criticisms of a work that had attempted to deal with the systematic botany of Gossypium. But Mr. Balls's anxiety that that great sin should not be attributed to him, exposes himself to the charge of deliberate disregard for both the methods and results of the systematist. It is a fact that I specially devoted a considerable part of my remarks to what I regard as the weak side of Mr. Balls's book, and I repeat it is a very weak side, which, though contained in one chapter mainly, dominates his entire studies of the cotton plant. But with equal deliberation, however, I recognised and even extolled the meritorious features of the book, which are undoubtedly very great.

The implication that I read only certain portions of Mr. Balls's book is quite uncalled for. As a matter of fact, I read every word. It was only because I appreciated and even admired the book that I felt it incumbent to express my mind unhesitatingly. It was in no spirit of carping that I gave special attention to its shortcomings. The issue at stake is very great indeed; namely, the development of the cotton staple, a problem of Imperial interest in the agriculture and industry of our Empire. I cannot help repeating, therefore, that for Mr. Balls to attempt to justify Mendelian cross-breeeding of undetermined stocks (and even pedigree selection of such stocks) of Gossypium is not only a blemish but a serious blunder, both in his book and his work. With culture experiments accuracy, in the starting point (more especially with stocks that of necessity involve several species and numerous varieties and races), is more essential than even care in subsequent treatment. We have heard far too much of the assumption that successful stocks can be produced in the laboratory or the experimental plot, in utter disregard of systematic botany.

The sneer that has been thereby cast on herbaria work is uncalled for, and merits the severest condemnation. Such an attitude may enlist the sympathy of the ignorant, but can secure no advancement in the object in view. The question of the future supply of cotton to the British looms is too serious a matter to justify any half-measures. The history of cotton is full of fads and fancies. Extravagant and wasteful experiments have taken the place of rational development. We have failed because we have not followed nature with sufficient closeness. We require the earnest endeavours of the experimental physiologist to be combined in the closest association with the most extended and searching investigations of the systematist. Either alone must of necessity be useless.

Mr. Lawrence Balls informs us that his description of "Gossypiæ" as a sub-order (instead of a tribe) had been taken from "an accepted authority on systematy." He might have favoured us with the name of the author in question. I have searched through a fairly extensive botanical library and failed to discover the authority to whom he may be alluding. Bentham and Hooker, in their "Genera Plantarum," place Gossypium in the tribe Hibisceæ (which Mr. Balls renders as Hibiscæ), but they make no mention of a sub-order "Gossypiæ" (? Gossypeæ). These are no doubt trivial criticisms and are made only in the spirit of "Hindu" and "Hindi." But admitting the "accepted authority on systematy," is there any advantage in setting on one side the universally accepted authorities on British botany?

I am afraid Mr. Lawrence Balls simply tries to obscure the main issue, raised in my review, by citing an example of careless orthography; the "Hindu" and "Hindi-weed" already mentioned. Is it necessary to explain that the word "Hindu" denotes the people or the religion, while "Hindi" and "Hindustani" indicate the languages of certain portions of India? These are their most general acceptations, but neither could, strictly speaking, be used as the name of a plant, more especially when *that* plant never could have come from India. The person who first used that name, in its Egyptian signification, was very possibly a follower of the school that seems to hold the view that accuracy in systematic botany was an unpardonable offence. De Candolle, long years ago, told us that the aim of science was not to make names, but to use names to distinguish plants. Does "Hindi-weed" isolate a certain cotton plant from all others? If it does not, it is a vulgar name that should find no place in a scientific publication.

Sir George Watt's "Wild and Cultivated Cotton Plants of the World" (to which Mr. Balls refers us) mentions Hindi-weed as being possibly a recessive hybrid of the *Moqui* of Arizona, or perhaps rather of the *N'dargua* cotton of Senegal. It is not advanced as a name that can be accepted as distinguishing a definite plant. But Mr. Balls himself is quoted by Sir George (*loc. cit.*, p. 182) as holding that Hindi-weed "hybridises with the others and the Mendelian splitting forms from the cross are very common, and also go under the name of 'Hindi,' though they are usually very tall, up to three metres. 'Hindi' itself is about one metre high, and except in its seed reminds me of American Uplands." We are thus told, by an advocate of non-systematic studies, that "Hindi-weed" may assume numerous forms and conditions until a certain example of it might have to be spoken of as not being Hindi-weed. Thus that vulgar Egyptian name is by no means as "definite as any other," though Mr. Balls in another passage assures us that it is. It is a loose, popular name that could never be taken seriously as the name of a cotton plant. The issue raised by Mr. Balls as to the Hindi-weed having a naked seed, while he seems to affirm that Sir George Watt "during the primary division of the genus" places it with fuzzy-seeded forms (a passage I have failed to discover) is, however, outside the scope of a review of Mr. Balls's book.

Lastly, I admit that Mr. Balls's jest of scientific names being merely useless duplicates of easier names was not only feeble (as he now admits it to have been) but highly misleading and utterly out of place.

THE REVIEWER.

THE KARAKORAM EXPEDITION.

THE account of Cav. Dr. F. de Filippi's expedition of 1914–15 to the eastern portion of the Karakoram range, briefly noticed in NATURE of August 5, has now been published in the *Geographical Journal* (vol. xlvi., No. 2), with a selection from the beautiful photographs taken by Capt. Antilli, to whom this part of the varied and

important work undertaken by the expedition was entrusted, together with a report of the interesting discussion which followed the reading of the paper. By the kind permission of the Royal Geographical Society we are now enabled to reproduce two of the views exhibited at the meeting on June 14, illustrating the characters and surroundings of the Remo glacier, which in some respects appears to resemble the great ice streams of the Arctic regions rather than those of the usual Himalayan type.

In general the Himalayan glacier, like that of the Alps, is confined to a single drainage system, and is separated from its neighbours by an ice-free ridge. But here we see the Remo not only spilling over the saddles which surround its upper basin, into the valley of the neighbouring Siachen glacier, but actually sending a tongue across the main watershed dividing the Indus drainage from that of Central Asia (Fig. 1). Again, the fact noticed by Dr. de Filippi, that the front of the Remo glacier is almost free from moraine matter, is without parallel among the larger glaciers of the Himalaya, where one may often clamber for miles beyond the snout over heaped-up masses of débris, and scarcely detect a vestige of the ice beneath. The moderate dimensions of the mountains that rise above the Remo glacier, as compared with its breadth, no doubt account for its immaculate appearance, so vividly described in the paper (Fig. 2).

The difference in aspect between the surroundings of the Remo glacier and those of the glaciers further west and in Sikkim, a point raised by the President at the close of the discussion, is perhaps to be explained in part by the geological structure of the district. The line of division between the crystalline rocks constituting the main axis of the Himalaya and the softer slates, shales, and limestones of Palæozoic and Mesozoic age which succeed them on the north, is shown on Lydekker's geological map of Kashmir (Memoirs, Geological Survey of India, vol. xxii.) as passing diagonally across the Karakoram range to the west of the Siachen glacier; and in the last note made by Stoliczka, two days before his death, he records the presence at the Karakoram pass of shales and limestones of Triassic and Liassic age. Thus the material from which the magnificent pinnacles of the western Karakoram, or the precipices of Kinchinjunga, have been carved out is lacking in the eastern extension of the range. Moreover, the absence of a deep gorge in close proximity to the crest of the range, like that of the Indus further west, or of the Tista in Sikkim, lessens the transporting power of the tributary

FIG. 1.—Sources of the River Yarkand. From the *Geographical Journal*, August.

torrents, and causes the hills to become smothered in a mantle of their own débris, so that, as Stoliczka remarks, "it becomes almost an exception to observe a rock *in situ*," and the scenery becomes correspondingly tame.

The occasion of the reading of Dr. de Filippi's paper was memorable in more respects than one. Not only was an opportunity afforded, and happily utilised by the President of the Society, of expressing the cordiality of our relations with Italy, whether we are engaged together in peaceful exploration or in the more serious business of war, but also by the participation in the discussion of the father of Himalayan exploration in that region, Col. Godwin-Austen, and of another pioneer in Central Asian discovery, Sir F. Younghusband.

FIG. 2.—Middle portion of Remo Glacier, Northern Branch. From the *Geographical Journal*, August.

THE EFFECT OF RADIUM ON THE GROWTH OF PLANTS.

AMONG the many remarkable properties of radium it was perhaps natural to expect that it might have some definite effect on plants, and even, under suitable conditions, cause sufficient increase in the amount of growth to justify its use in horticulture and agriculture. The early observations of Dixon and Wigham[1] at Dublin, however, did not seem very promising: 100 seeds of cress (*Lepidium sativum*) were uniformly distributed over an even surface of moist quartz sand, and after germination had taken place a sealed tube containing 5 mgms. of radium bromide was set 1 cm. above the central seed. The seedlings grew up, but without any curvature indicating positive or negative "radiotropism," and the only noticeable effect was a slight depression of growth in those within 1 cm. radius of the tube. As stronger preparations of radium became available more definite retardations and inhibitions were observed: thus Gager, in an elaborate report,[2] noted a more or less complete inhibition in cell activities in younger and especially embryonic tissues, with few exceptions. The action of radium through the soil, however, was different; germination and growth were both accelerated, and the plants furthest away were stimulated most. Acqua[3] found that different plants, and even different organs of the same plant, were differently affected, the root system in general responding more markedly than the aerial parts,

[1] Proc. Roy. Soc. Dublin, 1904, x., 178-192.

[3] *Ann. Bot.* (Rome), 1910, viii., 223-238.

and in his experiments being arrested in their development.

The intensity of the radiation is important, and G. Fabre,[4] using *Linum catharticum* as test plant, was able to obtain increased development and germination of seedlings by working with emanations up to 1·5 microcuries per 2 litres of air, and to retard development by using emanations of 40 microcuries per litre of air. H. Molisch[5] obtained a like result: young plants of vetches, beans, sunflower, etc., were stimulated in growth by weak emanations, but checked or entirely stopped by stronger ones. He further claimed that the "rest period" could be broken by the radium emanation, and forced lilac into bloom in November by attaching pipettes containing small quantities of radium chloride to the terminal buds.[6] In his earlier experiments he, like Dixon and Wigham, failed to detect any radiotropism, but later on he found indications in the case of certain heliotropically sensitive plants, *e.g.*, oats and vetches.[7]

These and similar results naturally suggested that the residues left after the extraction of radium, but still containing radioactive material, might have definite manurial value, and it was not long before definite statements were forthcoming. Baker[8] claimed that increased yields of wheat and radishes had been obtained by mixing one part of radioactive material (2 mg. ra. per ton) with ten of soil. It is true that Stoklasa's[9] results were negative (although in his other experiments radium emanations increased growth to a marked extent), but this did not prevent the introduction of radioactive fertilisers, and the enterprising syndicates and companies concerned were by no means loth to push their wares. The staffs of the agricultural experiment stations being busy people and, moreover, somewhat sceptical about plant stimulation on account of some rather sad failures, did not generally take the matter up, and it remained for Mr. Martin Sutton to carry out the necessary tests.

Mr. Sutton's experiments were made with radishes, tomatoes, potatoes, onions, carrots, and marrows, some grown in pots, others in plots out of doors. Eight different radium residues were used, in addition to pure radium bromide; the dressings were so arranged that equivalent quantities of radium were given in each case (1/4000 mgm. radium bromide to 15 lbs. of soil in the pots; 2½ times this amount per square yard to the plots). Controls were set up, including a set treated with the other substances present in the residues, designed to ascertain whether those had any effect.

The results have just been issued by Mr. Sutton. Going carefully through them, one is forced to the conclusion that the radioactive materials have been ineffective. In no case is there any clear evidence of increased growth. Even the pure radium bromide seems to have done nothing. We are therefore left with an apparent discrepancy. The work of the physiologists, assuming it to be sound, certainly indicated that radium emanation is capable of stimulating certain cell activities. Mr. Sutton's results show that such stimulus, if it exists at all, does not affect the final growth of the plant. The discrepancy is not a new one, it is periodically confronting the agricultural investigator. Thus Dr. Winifred Brenchley, at Rothamsted, has failed to obtain increases in growth by supplying plants with inorganic poisons which have been supposed to stimulate certain cell functions in suitable dilutions. The result opens up the prospect of an interesting discussion, but it also shows the danger of arguing from a simple physiological observation to a complex phenomenon like the growth of a plant in soil.

PROF. E. A. MINCHIN, F.R.S.

IT is with profound regret that we announce the death, on September 30, at Selsey, of Prof. E. A. Minchin, F.R.S.

Edward Alfred Minchin, younger son of Charles N. Minchin by his wife Mary J. Lugard, was born in 1866. From his birth he suffered from a constitutional weakness, and indeed his life was despaired of at first. He grew stronger with age, yet the premature close of his career was no doubt due to the physical disabilities against which he had so bravely struggled to the very end. Unable to share in the rough life of the ordinary schoolboy, he was educated privately, and then for a short time at the United Service College, Westward Ho! When about fourteen years of age he went to the Bishop Cotton School at Bangalore after having joined his parents in India. Here he lived happy years, free to indulge to his heart's content that love of animals and of natural history of which he had already shown signs in his childhood, sometimes to the consternation of his nurse. He made valuable collections, and developed early his keen powers of observation.

Although Minchin had distinguished himself at school by his aptitude for the classics, it was to natural science that he devoted himself in his university career at Oxford. He obtained an exhibition at Keble College, and took his degree in 1890 with first-class honours in zoology. Shortly afterwards he was awarded the University Scholarship at Naples, and then the Radcliffe Travelling Fellowship. In 1893 he was elected Fellow of Merton College. He was thus enabled to travel abroad to pursue his researches in foreign marine zoological stations, and to work in the laboratories of Prof. Bütschli, in Heidelberg, and Prof. R. Hertwig, in Munich. For several years assistant to Sir Ray Lankester and demonstrator in comparative anatomy at Oxford, he afterwards became lecturer in biology at Guy's Hospital, but soon succeeded Weldon in the Jodrell chair of zoology at University College, London, in 1899.

When, seven years later, a new chair of protozoology was founded in the University of London, Minchin was naturally chosen to fill the post, and undertook the direction of the new department of protozoology at the Lister Institute of Preventive Medicine in Chelsea. Here, to some extent freed from routine work and administrative worries, he pursued his researches with untiring industry, and reached those brilliant results which have made his name famous among protozoologists the world over. In 1910 he was awarded the Trail Medal, and in 1911 was elected a Fellow of the Royal Society. He married Florence Maud Fontain in 1903.

Even as an undergraduate Minchin made his mark as a student of singular ability and originality. His first scientific paper, "On a New Organ in Periplaneta" (*Quart. Journ. Microsc. Science,* vol. xxix., 1888), and a short note on the embryos of Aurelia (*Proc. Zool. Soc.*, 1889), were published before he had taken his degree. Shortly after, he gave the first intelligible account of the working of the extraordinary Cuvierian organs of Holothuria.

But space will allow us here to mention only a few of Prof. Minchin's numerous and valuable contributions to zoological science. He was a specialist in the best sense of the word, deliberately restricting the field of his researches in order to probe the more deeply into the mystery of life. The Porifera and the Protozoa were his favourite groups.

A series of papers, published from 1892 to 1898, on the structure, development, and classification of Calcareous Sponges placed Minchin at once in the first rank of zoological investigators. He was struck with the importance of studying specimens living under natural conditions or preserved in perfectly fresh state. An expert swimmer and diver, he loved to observe his sponges on the rocky coasts of Plymouth, Roscoff, Banyuls, and Naples. He was thus able to solve many of the problems which had baffled the efforts of his predecessors, and to correct not a few of their mistakes. These studies culminated in a masterly and beautifully illustrated memoir on the development of the spicules of the Clathrinidæ (*Quart. Journ. Microsc. Science,* vol. xl.), a triumph of technical skill over the difficulties encountered in dealing with minute histological details. It is typical of all his work: neat and methodical in preparation, accurate and thorough in execution, clear and convincing in presentation. To reach the high standard of accuracy he aimed at, Minchin worked with extraordinary patience and care; no pains were spared, no detail however small was neglected, every refinement of method brought into use. His mastery of technique was indeed remarkable, and great was his ingenuity in devising improvements in the instruments used and routine followed in his investigations.

In later years he devoted more and more of his time to the study of the Protozoa, especially of the parasitic forms. The same skill and care which had yielded such successful results in the study of the Porifera soon won for Minchin a high reputation among protozoologists. In 1905 he spent some time in Uganda on the Royal Society's Sleeping Sickness Commission. From that time his work was confined almost entirely to the elucidation of the life-history of the Trypanosomes. For years he devoted himself to this difficult problem, and the memoir brought out, in conjunction with Mr. J. D. Thomson, last January (*Quart. Journ. Microsc. Science,* vol. lx.), describing in every detail the life-history of *Trypanosoma lewisii* in the rat-flea, will remain a lasting memorial to Minchin's boundless industry and perseverance. Some idea of the magnitude of the work may be gathered from the fact that more than 1600 fleas were dissected and examined in the course of these researches. Among the important discoveries there described may be mentioned the occurrence of an intracellular stage passed through by the Trypanosome in the stomach of its host. Incidentally, Minchin contributed valuable information concerning the life-history and structure of the tsetse-fly and the flea.

It was not, however, by his original researches alone that he advanced zoological science. He wrote many excellent articles in the "Encyclopædia Britannica" and elsewhere, and text-books of the highest merit. The parts he contributed to Lankester's "Treatise on Zoology," dealing with the Porifera and the Sporozoa, are models of clear description and sound judgment based on wide zoological experience and a thorough knowledge of the literature. The later "Introduction to the Study of the Protozoa" is by far the best text-book yet written on the subject in English, or perhaps in any language, and will long remain a standard work.

Minchin had a wholesome horror of hurried or slipshod work, of anything which savoured of sensationalism or self-advertisement. He was always ready to give of his best, whether in his writings or his lectures, whether to his friends or his pupils. As a teacher he was particularly successful at the Lister Institute, where he welcomed and encouraged any who wished to engage in research. There also he lectured and gave practical instruction to students, many of whom were medical men from India and the tropics.

Minchin was a man of cultured intellect and wide interests, with a keen appreciation of the beauties of ancient and modern literature. His published works and his presidential addresses to the Quekett Microscopical Club are distinguished not only for the matter they contain, but also for the admirable form in which it is presented. Nowhere, perhaps, is this better seen than in his last scientific contribution, the presidential address to Section D of the British Association at Manchester. Unfortunately he was prevented from reading it himself by the illness which was so soon to carry him off.

The sudden ending of his scientific career will be deeply felt in the zoological world, not only in England, but also abroad, and especially perhaps in France, where his merits were quickly appreciated. Minchin's great modesty and his

gentle and unassuming character endeared him to his many intimate friends and pupils. His personal charm was greatly enhanced by a keen sense of humour; he delighted in a good story. In conversation Minchin was gifted with a happy turn of phrase. His friend, Mr. Heron-Allen, with whom he spent his last days, tells us that in answer to a quotation from O. W. Holmes, that "Life, as we call it, is nothing but the edge of the boundless ocean of existence where it comes on soundings," Minchin replied, "And death, as we call it, is nothing but the unfathomed deeps of the ocean of existence where we lose the sounding plumb."

DR. T. ALBRECHT.

WE deeply regret to announce the death, on August 31, at seventy-two years of age, of Dr. Theodor Albrecht, departmental chief in the Royal Prussian Geodetic Institute, Potsdam, and chief of the International Bureau for Investigating Latitude Variation since its inception in 1898. By his death, geodesy loses a painstaking and conscientious worker, who laboured zealously to unravel a complicated problem, and to carry forward the investigations so brilliantly inaugurated by the late Dr. Chandler. For many years he occupied himself with the study of the minute changes in the position of the earth's axis, and by his office had been mainly responsible for the methods of observation applied, and the trustworthiness of the results derived.

Prof. Fergola, as is well known, urged the necessity of attacking this question of latitude variation by a uniform and systematic method of observation under international control, so far back as 1883, but it was not until twelve years later that any progress was made, when Profs. Forster and Helmert, supported by the hopeful researches of Chandler, were able to bring the far-reaching scheme to fruition. From that time onward, Albrecht was identified with this plan, to which he gave untiring devotion. Even before his appointment as director, he had signalled his interest in these researches by dicussing the motion of the pole in the interval 1890–95, from observations made at some dozen observatories in Europe and America. Since then Dr. Albrecht issued reports with praiseworthy regularity, and his diagrams showing the excursions of the pole have been models of clearness. Under his superintendence the bureau justified itself by its diligent, patient labour and skill in handling minute details. Criticism has not been wanting, but probably there was little room for originality or brilliancy of treatment.

The late director performed a useful work in keeping an interesting problem before the scientific world, and though in these days there must be great difficulty in maintaining an international bureau, supported by the varying subsidies of many nations, amounting in all, we believe, to about 3000*l*. per annum, it would be a matter of regret if any breach of continuity in the conduct of the bureau should result.

NOTES.

AT the recent meeting in Manchester, the General Committee of the British Association unanimously adopted the following resolution, which has been forwarded to the Prime Minister, the Chancellor of the Exchequer, and the Presidents of the Board of Education and of Agriculture and Fisheries:—"That the British Association for the Advancement of Science, believing that the higher education of the nation is of supreme importance in the present crisis of our history, trusts that his Majesty's Government will, by continuing its financial support, maintain the efficiency of teaching and research in the universities and university colleges of the United Kingdom."

THE urgent need for a wise economy in every department of public and private life is recognised by every patriot anxious to see the war brought to a successful end. A timely protest in the Press from Sir James Yoxall, M.P., against unintelligent and wrongly directed economy deserves notice. At no time in the country's history has it been more necessary that every effort should be made to make our system of education efficient and thorough, so that when military conflict gives place to industrial competition we may be able to hold our own with the central European States. Yet Sir James Yoxall has to direct attention to attempts to save money at the expense of the education of the nation's children. "Supplies of books, stationery, and other needed school appliances are being lessened in amount or reduced in quality; plans are laid for abolishing evening classes and schools; and there is evidence of a wide general slackening in educational provision." Some local education authorities have contemplated reducing the salaries of teachers. "The Amalgamated Association of Operative Cotton Spinners, operatives themselves, and many of them parents, are asking that children may go into the mills to work full time at the age of thirteen. Agricultural people demand 'half-time' for children of eleven; and so does the Cotton Spinners' Trade Union, I understand." Such unwise economy must be discouraged everywhere, and it is the duty of every influential person to do his part to prevent any deterioration in the work of our schools and colleges, because upon it our country's welfare ultimately depends.

MR. E. W. SWANTON has been elected president of the British Mycological Society.

THE Thomas Hawksley Lecture of the Institution of Mechanical Engineers will be delivered on Friday, October 29, by Dr. Dugald Clerk; the subject will be, "The World's Sources of Fuel and Motive Power."

A PRELIMINARY meeting to discuss the formation of a proposed Society for the Study of Geological Physics will be held at the rooms of the Geological Society of London, Burlington House, W., on Thursday, October 14, at 3.30 p.m. The chair will be taken by Prof. Benjamin Moore.

THE issue of *Science* for September 17 announces the death of Prof. Karl E. Guthe, professor of physics in the University of Michigan and dean of the

Graduate School; and of Prof. J. H. Van Amringe, dean of Columbia College, and professor of mathematics until his retirement five years ago after a service of fifty years.

THE Rome correspondent of the *Morning Post* states that in consequence of comments on his Germanophil attitude, the Marquis Cappelli has resigned the presidency of the Royal Geographical Society of Italy, and the resignation has been accepted. As the Marquis Cappelli is also president of the International Agricultural Institute, the question is being asked whether he will now retain that position.

THE director of the Meteorological Office reports that information has been received from the seismological observatory at Eskdalemuir, Langholm, Scotland, of the record of a large earthquake which occurred at 7 a.m. G.M.T. on Sunday, October 3. The computed position of the epicentre is between Colorado, U.S.A., and the Island of Guadelupe, off the coast of California.

WE learn from the *Pioneer Mail* that the programme of the Board of Scientific Advice for India during the year 1915–16 includes the following work of the various scientific departments:—The meteorological department will continue observational work with pilot balloons at various stations, and will also do some experimental work on vertical air currents at Agra. In the astronomical department a new spectroheliograph is under construction, which it is hoped will be completed during the year. Five Omori seismographs, two at Simla, two at Calcutta, and one at Bombay, the Milne seismograph at Kodaikanal, and several instruments of local manufacture at Bombay, will be kept in use during the year for scientific research work. Geological surveys will be continued in Bombay, Central India, Rajputana, the Central Provinces, Burma, and Kashmir. In connection with the botanical survey of the country, the curator of the herbarium and the systematic assistants will work up, with a view to publication, the material of the past year's exploration in Southern India, and the material presented by contributors not belonging to the department for field work. It is proposed to continue the exploration of Travancore by the curator of the herbarium and an officer of the department. This field work will be of practical use in connection with the flora of Madras now under preparation. In the industrial section of the Indian Museum plant breeding and plant improvement work will be continued on wheat, tobacco, gram, fibre plants, indigo and oilseeds; and fruit entomology will include general investigations of crop pests, and especially of the pests of rice, sugar-cane and cotton, fruit trees, and stored grain. Under the head of agriculture, the following are among the lines of work in progress:—The combination of irrigation and drainage in the growing of rice; the study of the inheritance of the more important characters of dairy cattle by crossing; the building up of milk pedigree in cattle by selection.

THE Rev. Cyrus Byington, born in 1793, served for fifty years as a missionary among the Choctaw Indians, and died full of years and honour in 1868. He translated into Choctaw several books of the Old and New Testaments, and compiled a grammar of the language. His chief work was a Choctaw-English Dictionary, which he left in manuscript without final revision. This has now been done by Mr. J. R. Swanton with the assistance of Mr. H. S. Halbert, who spent many years among the Choctaws, became familiar with their language, and is an enthusiastic student of everything relating to the past history and present culture of the tribe. The dictionary, which has now been published as Bulletin 46 of the Bureau of American Ethnology, will be welcomed by all students of the languages of the American Indian tribes.

IN *Man* for October, Mr. T. E. Peet discusses the types of megalithic monuments found in the peninsula of Sinai, which are interesting in connection with the question of rude stone monuments in the Mediterranean basin, and also in view of a possible relation between their builders and the early Egyptians. The monuments consist of beehive tombs, rock circles, and hut circles. Much further investigation is needful before their origin and relations can be fixed with certainty. Mr. Peet, who writes with commendable caution, thinks that the evidence does not satisfactorily prove their connection with Egypt. As regards the Mediterranean relations, he remarks that the more specialised features of the true megalithic system—dolmens, the use of really large stones, and the combination of large orthostatic slabs and corbelled courses of masonry, as found in Malta and Sardinia —do not exist. Possibly further investigation may provide examples of these features, but at present we lack evidence to connect Sinai with the Mediterranean megalithic area.

IN the Journal of the College of Agriculture of the Imperial University, Sapporo, Japan (vol. vi., pt. vii.), Mr. J. Yamare discusses the inheritance of "notched" ears in Ayrshire cattle. This marked abnormality recognised in American herds of the breed is due to a Mendelian dominant factor, but it is of interest to find that heterozygote individuals show the "notching" only in a greatly reduced condition.

STUDENTS of the Dragonflies will welcome Mr. Clarence H. Kennedy's "Notes on the Life-history and Ecology of the Odonata of Washington and Oregon" (Proc. U.S. Nat. Mus., vol. xlix, pp. 259–345). The habits of the insects when pairing and egg-laying are described, and structural details of the nymphs and of the imagos at different ages are made clear by means of an excellent set of illustrations.

DR. A. E. CAMERON has spent a year in New Jersey as a research fellow of the Victoria University, Manchester, and gives some of the results of his studies in an article on potato spraying and dusting, published in the Bulletin of Entomological Research (vol. vi., part i.). It is established that Bordeaux mixture with arsenate, in addition to its effect as a fungicide, kills the beetle-enemies of the potato crop. Dr. Cameron directs especial attention to the profitable

co-operation found in the United States between scientific experts, farmers, and chemical manufacturers, and wishes that similar conditions might be brought about in this country.

THE trustees of the British Museum have issued an account of the Nemertine Worms collected on the *Terra Nova* Antarctic Expedition (Nat. Hist. Report, Zoology, vol. ii., No. 5), by Mr. H. A. Baylis. The number of species is small, and most of them are represented by few examples, but the author in his systematic and anatomical descriptions and drawings has made the most of the material at his disposal. Worms from Antarctic localities described by other naturalists as species of Cerebratulus and Eupolia, are all referred to M'Intosh's Kerguelen species *Lineus corrugatus*, which, on this view, has an extensive circumpolar range.

A VALUABLE account of the penguins of South Georgia, by Mr. R. C. Murphy, has been published, in the form of a bulletin (vol. ii., No. 2) by the Brooklyn Institute of Arts and Sciences. The charge of wanton slaughter, which the author makes against the crew of the *Daisy*, a sealing brig which he accompanied for the purpose of studying the penguin rookeries, makes painful reading. It would seem that the doom of the king penguin, so far as South Georgia is concerned, is sealed. In addition to his studies of this bird, Mr. Murphy gives some lengthy notes on the Gentoo penguin (*Pygoscelis papua*). Since so much has already been written on these birds, more than Mr. Murphy seems to be aware of, judging from his references to the literature of this subject, it is not surprising to find that the author has nothing new of importance to record. In one particular he has missed a fine opportunity. We have heard much of the central "pouch" and of the "flap of skin" under which the king penguin incubates its egg, and later broods its young, but so far no really careful, or accurate, description of this structure has yet been given. Mr. Murphy has done nothing to help forward the solution of this matter.

THE Geological Survey of Great Britain describes the mainland portions of Sheets 330 and 331 in a memoir by H. J. O. White on "The Geology of the Country near Lymington and Portsmouth" (1915, price 1*s*. 6*d*.). The district includes the admirably fossiliferous strata of Bracklesham and the Oligocene beds of Brockenhurst, where a band occurs in the Headon series that is more purely marine than its representative in the Isle of Wight. It is stated that the drowned valley of the Solent and the inlets near Portsmouth generally have been considerably enlarged by marine erosion.

THE United States National Museum has received from a marine Miocene formation in California the greater part of the skull of the rare Sirenian Desmostylus, which shows that in several respects this is one of the most primitive genera of its order. The snout is not bent downwards so much as in modern sirenians, and the nostrils are comparatively small and far forwards. The new specimen is described in detail by Dr. O. P. Hay in the Proceedings of the United States National Museum, No. 2113, and reference is also made to an allied species found on the opposite coast of the Pacific in Japan.

THE difficulty of restoring extinct reptiles, even when nearly complete skeletons are known, is well illustrated by the armoured dinosaur Stegosaurus, described by Mr. C. W. Gilmore in a recent part of the Proceedings of the United States National Museum (No. 2110). When Marsh first found the greater part of a skeleton of this reptile, he supposed that its large plates of bony armour were arranged as a ridge along the middle of the back; subsequent authors recognised that the plates were not median, and regarded them as forming a paired series; Mr. Gilmore now concludes that the plates were neither median nor paired, but must have formed two alternating series along the middle of the back. He also thinks that the largest plates were above the root of the tail, not above the pelvis, and thus he feels obliged to make the trunk shorter than in previous restorations. A readjustment of the head gives to Stegosaurus the appearance of a browsing animal.

THE *American Journal of Science* for September, 1915 (vol. xl., No. 237), contains two papers of special geological interest. W. M. Davis gives the results of his studies, during 1914, of the coral-reefs of the Pacific, and strongly supports the theory put forward by C. Darwin "when he was twenty-five years old and before he had ever seen a true coral-reef." W. H. Twenhofel discusses the making of black shale, such as that in which graptolites abound. He shows, from a remarkable instance on the Esthonian coast, described by several Russian writers, that black slimes are not necessarily deposits of deep water, but may fill up coastal shallows. The blackness is in this case due to hydrocarbons of vegetable origin; the absence of tides, and a cool temperate climate are favouring conditions. "Sulphur gas" is present, and the author believes that animal remains would ultimately be pyritised in such an environment. Anærobic bacteria probably play a large part in the production of the slime. The muds of the Black Sea are contrasted with these shore-deposits.

THE August number of *The Royal Engineers' Journal* (vol. xxii., No. 2) contains a lengthy summary of General Maitrot's study of the strategical relations of France and Germany. The original appeared in French in a third edition this year as "Nos Frontières de l'Est et du Nord," and while in the main it deals with military considerations, contains a valuable study of the geography of the western theatre of war. Major W. A. J. O'Meara's summary is accompanied by several useful maps from the original publication. Events have proved the accuracy of General Maitrot's estimate of the value of the geographical factor in the plan of campaign.

INVESTIGATIONS of ocean currents around Australia have been made by floats thrown overboard from various vessels. A chart indicating the drift of fifty of those which have been recovered from the end of 1909 to the middle of 1914 has been published by the Commonwealth Government. Most noticeable is the

E.N.E. course of those set adrift in the forties in contrast to the general E.S.E. track of those from the thirties south of Australia. As most of the floats were cast up on relatively unfrequented shores where they may have lain a considerable time before discovery, it is impossible to form any estimate of their rate of travel. Nor can any conclusions be drawn from the absence of floats on a coast, as, for example, the western coast of the south island of New Zealand, where none have been found; this may be due to that coast being less frequented than the western coast of the north island, where many were picked up.

THE rainfall in Australia in 1914 is shown in a series of charts prepared by Mr. H. A. Hunt, and issued by the Commonwealth Government. The year was noticeable for its drought, and in South Australia, the Riverina, western Victoria, and much of Tasmania it was the driest year on record. These conditions resulted in a failure of the crops over the greater part of the wheat belt, with a production only some 30 per cent. of the previous season. Tasmania suffered least of all parts of the wheat belt, but in other parts of southern Australia the deficiency of rain in the cool part of the year averaged from 25 per cent. to 72 per cent. These conditions were related to anti-cyclones of great intensity, which kept south of their normal track across Australia, and moved very slowly, with the result that the "Antarctic" disturbances failed to reach Australia to any great extent. The weakness and failure of the winter rains were partly counterbalanced in the warmer months by unusually strong monsoons. In western Australia, Victoria, central and southern New South Wales in November and December, these rains were far above the average. On the whole, the drought of 1914 was not so widespread as the droughts of 1888 and 1902, but was locally more intense. Queensland and tropical Australia largely escaped.

IN the *Tôhoku Mathematical Journal* (viii., 1) Mr. Kihizi Yanagihara, in a note entitled "A Theorem on Surface," offers a proof of the statement that if one surface always cuts a second surface in a plane curve or several simply closed plane curves, then the first surface must be a sphere.

IN a paper on "General Expression for Stress Components" (Proceedings of the Tokyo Mathematical Physical Society, viii., 2 (1915)), Mr. Senien Yokota considers the problem of an infinite plate containing a circular hole in which a plug can be inserted, or having complete or partial contact with its periphery. The plate is supposed to be under a uniform tension in a fixed direction. It would appear that whether the plug is loose or just fits the hole, the maximum tangential tension on the periphery of the hole is three times the tension applied to the plate. This result is no doubt of interest in connection with the problem of rivets.

IT is remarkable that while aeroplanes the engines of which have been disabled by shrapnel can pursue their erratic paths to earth without any prospect of having their equations of motion solved, mathematicians are still covering pages of formulæ with attempts to solve the problem of three (hypothetical) bodies. We have before us a paper by Prof. T. Levi Civita on "The Reduction of the Problem of Three Bodies" (Venice: Carlo Ferrari, 1915; reprinted from the *Atti del R. Istituto Veneto*, lxxiv., 2, pp. 907–939), and Mr. D. Buchanan discusses a new isosceles solution in the Transactions of the American Mathematical Society, xvi., 3, pp. 259–274. We can only hope that these and other writers on this problem will speedily bring their investigations to such a state of perfection as to render it impossible to discover anything further on the subject. When this is done, they will find aeroplanes clamouring for a little attention.

IN response to numerous requests for information as to the melting points of the chemical elements, the Bureau of Standards at Washington has issued a table of melting points according to the most trustworthy data. The following are the melting points on the thermodynamic scale used by the bureau as standard temperatures in the standardisation of thermometers and pyrometers: Mercury $-38.9°$, tin $231.9°$, cadmium $320.9°$, lead $327.4°$, zinc $419.4°$, antimony $630.0°$, aluminium $658.7°$, silver 960.5, gold $1063.0°$, copper $1083.0°$, nickel $1452°$, iron $1530°$, palladium $1549°$, platinum $1755°$, tungsten $3000°$. At temperatures of $1000°$ the uncertainty is of the order $0.1°$, at platinum $5°$, and at tungsten $100°$ C. A further table of other standard temperatures is given in which the following are included: normal boiling point of oxygen $-183.0°$, sublimation of carbon dioxide in an inert liquid $-78.5°$, normal boiling points of water $100°$, naphthalene $217.96°$, benzophenone $305.9°$, sulphur $444.6°$, freezing point of sodium chloride $801°$ C.

THERE is an interesting description with photographs in *Engineering* for October 1 of what is in many respects the most remarkable old steam engine in existence. This is a Newcomen engine used at the Farme Colliery, Rutherglen, near Glasgow. The valve gear is of the simplest possible kind, and is worked by hand, just as was the case with the original Newcomen engine. The engine is used for winding, and draws a cage up in 35 seconds, making 16 revolutions while doing so. The cylinder has a diameter of 2 ft. 8¼ in., and the stroke is 5 ft. 6 in. The mean pressure is 7·35 lb. per sq. in., and the boiler pressure is 3 lb. per sq. in. The maximum indicated horse-power is 27.

IN addition to the works referred to in the last two numbers of NATURE, the following forthcoming books of science are announced:—In *Agriculture*—The Spirit of the Soil: An Authorised Exposition of the Theories and Results evolving from Prof. Bottomley's Inoculation of Soil by Means of Bacteria, G. D. Knox, illustrated (Constable and Co., Ltd.); Poultry Husbandry, E. Brown, illustrated (E. Arnold). In *Anthropology and Archaeology*—Savage Man of Central Africa, Dr. A. L. Cureau (T. Fisher Unwin, Ltd.). In *Biology*—The Hill Birds of Scotland, S. Gordon, illustrated; Thirty-five Years in the New Forest, Hon. G. Lascelles, illustrated (E. Arnold); Trout Fly-Fishing in

America, C. Z. Southard, illustrated; The Rambles of a Canadian Naturalist, S. T. Wood, illustrated (J. M. Dent and Sons, Ltd.); Bramble-Bees, J. H. Fabre (Hodder and Stoughton); Bird Behaviour, F. Finn; Insect Artisans and their Work, E. Step (Hutchinson and Co.); The Book of the Wilderness and Jungle, F. G. Aflalo; Wild Animals of Yesterday and To-Day, F. Finn; The Common Beetles of our Countryside, W. E. Sharp (S. W. Partridge and Co.); Wonders of Animal Life, W. S. Berridge (Simpkin and Co., Ltd.). In *Geography and Travel*—By Forest Ways in New Zealand, F. A. Roberts, illustrated (Heath, Cranton and Co., Ltd.); Java: Past and Present, D. Campbell, 2 vols., illustrated (Heinemann); How to Read Ordnance Maps, J. F. Unstead; Philip's Human Geographies, H. Fairgrieve and E. Young (G. Philip and Son, Ltd.); With Scott: the Silver Lining, T. G. Taylor, illustrated (Smith, Elder and Co.). In *Geology*—Earth-Lays: Geological and other Moods, C. Tolly (J. M. Dent and Sons, Ltd.). In *Mathematical and Physical Science*—Text-Book of Navigation and Nautical Astronomy, Capt. A. P. W. Williamson, new edition, illustrated (John Hogg). In *Medical Science*—Mosquito Control in Panama: the Eradication of Malaria and Yellow Fever in Cuba and Panama, J. A. Le Prince and A. J. Orenstein (G. P. Putnam's Sons). In *Technology*—Handbook of Technical Instruction for Wireless Telegraphists, J. C. Hawkhead and H. M. Dowsett, new edition, illustrated (The Wireless Press, Ltd.). In *Miscellaneous*—The Limitations of Science, Prof. L. T. More (Constable and Co., Ltd.); Social Progress and the Darwinian Theory, G. W. Nasmyth; Darwin and the Humanities, Prof. J. Mark Baldwin (G. P. Putnam's Sons).

OUR ASTRONOMICAL COLUMN.

MEASURES OF JUPITER.—Numerous visual and photographic measures of the diameter of this planet have been made by the Rev. Father S. Chevalier, S.J., of the Zô-Sé Observatory, during 1912–13 (*Mem. Soc. Spett. Ital.*, July, 1915). The Gautier micrometer used in the visual work provides for the measures being made by bringing two strips of platinum tangential to the limbs of the planet, either (i) internally, *i.e.* with both strips seen in front of the disc, or (ii) externally, both strips beyond the disc. The two sets of measures thus obtained were of closely similar accuracy. In the photographic work very many separate exposures were made on each plate, affording material for a considerable body of measures. The exposures were graded in seven groups according to intensity, and measures on only four of these sets were used in taking the means. The discarded groups were those in which the images were considered either too small through under-exposure or enlarged by irradiation. The mean results may be summarised as follows:—

	Polar diam.	Equat. diam.
Visual measures ...	35·37″	38·16″
Photographic measures	35·20″	37·99″

The value of the aplatissement derived from both sets is practically identical, its reciprocal being 13·6, indicating a decidedly greater flattening than hitherto ascribed to this planet. Thus in one of the most important memoirs recently published (Lau, *Ast. Nach.*, No. 4673) the diameters are given as 35·4″ and 37·6″, yielding 17 as the reciprocal of the ellipticity.

THE ROTATION PERIOD OF CERTAIN JOVIAN MARKINGS.—Jupiter is now well situated for observation, and Mr. W. F. Denning, in the Journal of the Royal Astronomical Society of Canada (September), indicates some directions in which useful work may be done. The subject of the paper is the rotation period of the great red spot and of the hollow in the southern equatorial belt. The yearly values of the rotation period are tabulated for the eighty-four years, 1831–1914 (inclusive). Waiving the debatable point involved in the formation of this sequence, the period has varied between 9h. 55m. 33·3s. (1831) and 9h. 55m. 41·7s. (1898). Special attention is directed to the very marked acceleration since 1910. The mean period of rotation for about 74,170 rotations comes out at 9h. 55m. 36·9s. After such a weighty determination one hesitates to mention a value based on twenty-nine rotations, but M. Chevalier's recent photographic measures are worthy of note (*Mem. Spett. Ital.*, vol. iv., September 2, p. 113). The point measured was the western extremity of the south tropical disturbance, and the period deduced 9h. 55m. 10·4s. ± 0·7s., a faster movement than Mr. Denning assigns to the dusky south tropical disturbance (9h. 55m. 20s. approx.). The question of co-ordinating the visual and photographic observations would no doubt in happier times have led to extensive polemics.

R. CORONÆ BOREALIS.—This irregular variable has been manifesting light-changes during the past summer (see this column, August 19). We now learn from the Monthly Register of the Society of Practical Astronomy that in Bulletin No. 585 Harvard College Observatory, August 14, 1915, Prof. E. C. Pickering states that attention had been directed to its diminution in brightness by Mr. Eaton, and Mr. Bancroft found its magnitude 6·8 on July 24 and 6·9 on the 25th; whilst at Harvard, on August 13, its magnitude was only 7·7 (Mr. Campbell).

A 10-INCH DIFFRACTION GRATING.—A short paper by Prof. A. A. Michelson on the ruling and performance of a giant diffraction grating (*Proc. Amer. Phil. Soc.*, No. 217, p. 137) affords most inspiring reading. Rowland's gratings accomplished so much, yet the interferometer, the echelon, and the plane parallel plate brought such undreamed-of resolving powers into practical employ that it might well have been imagined that the grating had had its day. Michelson, the pioneer of the newer methods, realised early their disadvantages, and twelve years ago set about constructing a perfect screw 20 ins. in length, with the hope of some day ruling a grating 14 ins. long. Mechanicians will delight in the ingenious devices which have brought realisation within reach, and even encourage the undertaking of a 20-in. grating. Thus for correcting the screw an interferometer method was adapted enabling measurement to within 1×10^{-6} of an inch. An auto-collimating method of straightening the guiding ways ensured rectilinear motions within one second of arc. The grating carriage was nearly floated in mercury. Longitudinal movement of the screw was geometrically eliminated by allowing its spherically rounded end to bear against an optically plane surface of diamond fitted with adjustments to secure normality to the axis of the screw. Periodic errors could be corrected by using a worm-wheel to rotate the screw, and those of higher order were eliminated by a mysterious "correcting device." So long ago as 1910 a 6½-in. grating had been produced and was employed by Messrs. Gale and Lemon in a research demanding resolving powers rivalling those of interference spectroscopes; now a ruled surface 9⅜ in. × 2⅞ in., having 11,700 lines per inch, has been achieved and tested in a spectrograph of the Littrow form with an 8-in. 20-ft. Brashear lens. The

theoretical resolving power in the sixth order is 660,000, and 600,000 has actually been attained on a negative from which was prepared the illustration accompanying the paper.

THE SOLAR PHYSICS OBSERVATORY, CAMBRIDGE.—We have received a copy of the second annual report of the director relating to the year April 1, 1914, to March 31, 1915. Disadvantageous conditions arising out of the war have imposed serious limitations on the output of work, and have also retarded the installation of equipment. Mr. Baxandall has made considerable progress in working out the details of the chemistry stellar spectra for the projected atlas. The green regions of the spectra of α Cygni, α Canis Minoris, α Persei, and α Canis Majoris have been reduced, and the results are being prepared for publication. Spectra of several bright stars have been photographed in the course of adjusting the new spectrograph used with the 15-in. Huggin's refractor. Solar work has evidently been prosecuted both with zeal and success. The observers with the South Kensington spectroheliograph are especially to be congratulated on having secured spectroheliograms of the sun's limb on no fewer than 110 days. The solar eclipse expedition to Theodosia in the Crimea was very unfortunately foiled by clouds, and this is doubly regrettable as the eclipse provided some novel spectroscopic features. Successful photographs of sun-spot spectra have been secured with the McClean solar instruments. In the laboratory a powerful spectrograph of the Littrow type has been improvised, using a 6-in. plane grating and a 6-in. Cooke photovisual lens, and thus the 21-ft. concave grating detained at Odessa will scarcely be missed.

LONG-DISTANCE WIRELESS TELEPHONY.

THE announcement that the United States Navy Department has successfully experimented with a wireless telephone from Arlington, Virginia, to Mare Island, California, is chiefly interesting on account of the distance covered—2500 miles. If this success can be maintained in all conditions it will mark a notable achievement and one upon which the naval authorities in the United States may be complimented, because of the many years of steady and silent work which they have devoted to the subject.

There is nothing inherently impossible in long-distance wireless telephony, and from the scientific point of view there is no reason why it should not be carried on over even greater distances than that recorded above, but there are practical difficulties in regard to the construction of a microphone transmitter capable of passing large high-frequency currents, and in the production of the necessary persistent oscillations. In ordinary telephony, the current going through the microphone is quite small, and so long as the power to be dealt with is small, it is easily possible to obtain a microphone capable of dealing with the amount of energy while giving good articulation. But when a power measured in kilowatts has to be dealt with it is another matter. By using many microphones in parallel; by cooling the carbon granules with gas or immersing them in oil, and a host of similar devices, inventors have sought to produce one capable of dealing for protracted periods with a heavy current; but either they have not been entirely successful in this, or articulation has suffered. It is therefore desirable to await a full official account of the experiments carried out by the United States Navy Department before expressing an opinion upon the results. This is all the more necessary because of the great difficulty of judging the success of long-distance and other experiments merely by "reading."

It is extraordinary, in practice, to observe the marked difference between the distance at which speech is audible and the distance to which it is truly intelligible. The faint overtones and small nuances upon which intelligible speech depends are, at best, all too lightly impressed on the ever-varying curve of intensity sent out; and if they are smothered up or glossed over by a coarse microphone, a distant receiving station where the signals are weak gets only the bare fundamental tones stripped of all meaning. It is very easy to be deceived in this, and when well-known words are uttered, the ear glibly supplies the missing sounds.

EXPERIMENTS ON HOMING.[1]

PROF. J. B. WATSON and Dr. K. S. Lashley have made some important experiments at Bird Key, in the Tortugas, on the homing capacity of the noddy tern (*Anous stolidus*) and the sooty tern (*Sterna fuliginosa*), which breed there in large numbers. The island is peculiarly suitable for the purpose, since it marks the northern limit of the migration of these two tropical terns (so that if the birds are experimentally transported further north they find themselves in regions which they have not previously visited); moreover, on the westward side there is only the open water of the Gulf of Mexico until the shore-line of Texas is reached, Galveston being 855 statute miles distant. "This strip of open water proves a magnificent route for homing experiments." The authors caught terns at their nesting-places, put individual marks of paint on their head and neck, tied a small tag recording the date, locality, and marking round the neck, fixed a larger duplicate tag beside the nest, transported the birds in large cages to a distance, liberated them, and watched for their return. The general result is of great interest:—"The noddy and sooty terns can return from distances up to 1000 miles in the absence of all landmarks, at least so far as the term landmark is understood at present."

Some details of this careful piece of work may be noted, for they are very instructive. From Galveston (855 miles away) three birds returned out of ten, taking from about six to about twelve days; two noddies liberated at 720 miles both returned, taking between eleven and seventeen days; out of ten birds liberated at 585 miles eight returned, taking from about four to about eight days; out of four noddies and four sooties liberated in open water 461 statute miles away, two noddies returned in three days; of twelve taken north to Mobile, only one returned, taking about seven days; two noddies and two sooties carried in a state-room to Havana and released in the harbour there early in the morning of July 11, returned to Bird Key on the 12th, the distance in a straight line being about 108 statute miles; of three noddies and two sooties liberated off Cape Hatteras (850 miles to the north), both of the latter and at least one of the former species returned after several days. "The alongshore route, which is the one in all probability chosen by the birds on their return, since they were gone several nights, is approximately 1081 statute miles." (It seems that the birds almost never rest on the water, unless they happen to find pieces of driftwood or the like.) The records show that the terns often take as long for short distances as for long distances, and that a return from the open sea outside of all landmarks is just as practicable as a return from a coast.

By a series of exceedingly careful experiments Dr.

[1] Papers from the Department of Marine Biology of the Carnegie Institution at Washington. Vol. vii., "Homing and Related Activities of Birds." By J. B. Watson and K. S. Lashley. Pp. 1–104+7 plates+9 figs. (Washington: The Carnegie Institution, 1915.)

Lashley has shown that the problems of proximate orientation are relatively simple and straightforward. On the island of Bird Key the terns make their adjustment to the nest, mate, young, etc., on a basis largely of visual habits. Kinæsthetic habits are also involved, but to a less extent. On dark nights the sooty tern hovers over the crowded nesting area, giving out his call; he is answered by his mate and young, and is thus guided to the nest. Dr. Lashley found no evidence of any remarkable or unusual sensitiveness, or of the functioning of any hypothetical sense-organ.

As to the more difficult problem of distant orientation, the authors consider and dismiss various suggestions: that the birds follow water-currents; that they get their bearings by ascending to a great height; that they have special visual acuteness, *e.g.* to infra-luminous rays; or that they have special tactual or olfactory sensitiveness in the nasal cavities. The experimental thoroughness with which the spectral sensitivity and the functioning of the nasal chamber are dealt with is worthy of imitation. The authors are unwilling to suggest at present the assumption of any new and mysterious sense; they rightly prefer to continue to experiment. They suggest various experiments, *e.g.* on the sensory equipment of homing pigeons, and they conclude:—"We are far from being without hope that future studies may yield results which will enable us to solve the riddle which has been propounded to scientific men of all ages, but as yet never satisfactorily answered."

THE INSTITUTE OF METALS.

At the meeting of the Institute of Metals held in London on September 17, a number of interesting papers were read and discussed. Amongst these were the following:—"Specifications for Alloys for High-speed Superheated Steam Turbine Blading," by W. B. Parker. In this paper the author confines his attention to a consideration of the non-ferrous alloys which are used for turbine blading. He gives a clear description of the physical and chemical properties which are essential for this purpose, and discusses in detail the causes of the wearing and corrosion of the blades. It is pointed out that although non-ferrous alloys have the advantage of being non-rusting, they do not possess a good proportional limit which is capable of being retained for long periods when exposed at the temperature of highly superheated steam. This fact has so far prevented the use of non-ferrous alloys for this particular purpose, and steel alloys are invariably utilised. The proportional limit should remain, for temperatures between 100° and 450° C., within 10 per cent. of its value at the ordinary temperature. Investigation is, therefore, needed, in order to find either (1) a non-ferrous alloy which will almost indefinitely retain its hardness up to a temperature of 450° C., or (2) a steel which will fulfil the above requirements and also be non-rusting. Anyone conducting research along these lines will find Mr. Parker's paper extremely valuable.

"The Constitution of Brasses Containing Small Percentages of Tin," by Dr. Hudson and R. M. Jones. This paper deals with the constitution of the ternary alloys containing from 50 to 70 per cent. of copper and 0·5 per cent. of tin. The ranges in which the various constituents can exist, at temperatures below the lowest thermal critical points of the alloys, have been determined, and the results are embodied in a constitution diagram. Most of the alloys fall into one of the two following groups: (1) Those in which the tin is held in solid solution, and consequently possess the normal structure of the copper-zinc series, and (2) those in which a constituent is present, which is similar to the δ of the copper-tin alloys.

"A Thermostat for Moderate and High Temperatures." The authors of this paper, J. L. Haughton and D. Hanson, describe a simple and much-needed apparatus which they have designed for keeping constant temperatures for long periods. The records illustrated in the paper show that the apparatus is highly satisfactory. By using fused silica in the place of glass it is hoped that the effective range of temperature will be considerably extended.

"Metallic Crystal Twinning by Direct Mechanical Strain." In this paper Prof. C. A. Edwards gives evidence which proves that certain metallic crystals are twinned when subjected to mechanical deformation without the intermediate operation of annealing. In the case of tin the twinning is very marked, even at the temperature of liquid air. Diagrams are shown to illustrate the possible mechanism of twinning, and from a consideration of these it is concluded that amorphous layers are produced on the twinning planes.

"The Micro-chemistry of Corrosion," by Dr. Desch and H. Hyman. The corrosion of gun-metals has been examined by the electrolytic method. The presence of tin decreases the rate of corrosion by forming a layer of basic salts which act as a protective coating on the metallic surface. Coarsening the structure by annealing increases the corrosion. A pure alpha alloy is more readily acted upon than one which contains the eutectoid, but the presence of the beta, obtained by quenching, has very little effect.

ON THE FUNCTIONS OF THE CEREBRUM.[1]

The first of these papers is a study of thirty-eight cases of insanity (dementia præcox, general paralysis, arteriosclerotic dementia, and senile dementia) and their autopsies. It is pointed out that entirely different symptoms (hallucinations, delusions, loss of memory, disordered conduct) may occur in different patients, although the associated cortical atrophy may occur in precisely the same areas; also that the same symptoms may occur in different patients in whom the cortical atrophy is subsequently found to be in different areas. The author, however, ignores the fact that different *layers* of the cerebral cortex are affected in the different diseases.

The second paper is the result of an experimental study of cerebral localisation in monkeys. It is there pointed out that any given cortical motor centre (the leg area, for example) differs in size and shape in different animals of the same species, in the two hemispheres of the same animal, and even in the same hemisphere at different times. For instance, it is found that the arm can sometimes be stimulated from a spot in the middle of the leg area, sometimes not. From these data Dr. Franz draws conclusions as to certain possible connections between neurons. We are quite prepared to go even as far as this with him; but when he offers these neural arrangements as an explanation of "the variations of behaviour of different animals and of the same animal at different times to the same form of stimulation," we must join issue. Not so much that Dr. Franz's suggestions are incorrect from a neurological point of view

[1] (1) "Symptomatological Differences Associated with Similar Cerebral Lesions in the Insane." (2) "Variations in Distribution of the Motor Centres." By Shepherd Ivory Franz. (Princeton, N.J.: *Psychological Review* Co.)

as that they are insufficient to satisfy the requirements of psychology.

Both these papers are too materialistic, and take no notice of modern psychological research, which has demonstrated the paramount importance of *experience* in determining modes of reaction. This is especially remarkable in a publication issued in a series of "Psychological Monographs" by the "*Psychological Review* Company," of Princeton, N.J.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE address of the President, Prof. Grenville A. J. Cole, was a brilliant and stimulating commencement to the proceedings of this section. Following it came an interesting address by Dr. George Hickling on the geology of Manchester and district, in which he pointed out the excellent position of Manchester, both geographically and geologically, situated at the junction of the red beds and the coal measures, with a great variety of opportunities for field-work in the neighbouring Pennine Chain. Prof. E. J. Garwood followed with a paper on the discovery of Solenopora and Sphærocodium in the Silurian rocks of Britain. Up to the delivery of his presidential address at Birmingham these organisms had not been found in Silurian rocks, but careful search has now proved that Solenopora occurs both in the Wenlock and Woolhope limestones. In areas on the borders of Herefordshire and Radnorshire had been found crystalline limestones, upwards of 80 ft. thick, containing remarkable developments of these and similar algal growths, amongst which were the remains of Girvanella and Sphærocodium, the latter genus being now recorded for the first time from rocks in Britain.

Prof. W. Boyd Dawkins contributed two papers. The first was on the classification of the Tertiary strata by means of the Eutherian mammals, based on their evolution. The most important break in the succession of life-forms occurs at the close of the Oligocene period, since when there is a marked continuity showing that the present face of the earth is merely the last in a long succession in the Tertiary period. His second paper dealt with the geological evidence in Britain as to the antiquity of man. He agreed with Prof. Boule in regarding the evidence of the rostrocarinate eoliths found in East Anglia as of doubtful value. The Ipswich skeleton was obtained from a shallow pit of decalcified boulder clay (not boulder clay *in situ*) into Glacial sands, and was, he believed, a case of interment which might be of any age from neolithic to modern times. In the case of the Piltdown skull, he fully accepted Dr. Smith Woodward's opinion that the find belongs to the early Pleistocene period. The evidence indicated that man appeared in Britain and the Continent at the period when he might be expected to appear from the study of Tertiary mammalia—at the beginning of the Pleistocene age, when the existing Eutherian mammalian species were abundant. He may be looked for in the Pliocene, but in the older strata he can only be represented by an ancestry of intermediate forms.

On September 9 a joint discussion was held with Section E on the classification of land forms, which will be reported in the records of that Section. Afterwards Canon Bonney gave some notes on new sections in Charnwood Forest. Considerable quarrying had thrown light on sections previously described, which had caused him to modify his previous views. He was now convinced that the dominant Bardon breccia was really a very exceptional case of fluxion breccia. Prof. W. W. Watts followed with notes on the granite surfaces of Mount Sorrel. It had been suggested that some of the ground and polished surfaces known in this area and in certain other Midland localities might be due to wind action in Pleistocene times. A recently discovered section at Mount Sorrel showed glacial striæ crossing wind grooves at a high angle, proving that the Triassic wind grooves had survived actual glaciation.

Dr. A. H. Cox and Mr. A. K. Wells contributed an account of investigations on the Ordovician sequence in Cader Idris. Re-examination of the area had shown that the older views of the igneous rocks of this area, as all of Arenig age, must be modified. Four distinct volcanic centres in the Ordovician series had now been discovered. Prof. W. G. Fearnsides presented a preliminary account of investigations to prove the underground contours of the Barnsley seam of coal. The sites were plotted on a half-inch map, the depths to the coal were corrected for height above sea-level, and contour lines had been drawn among the spot-levels so obtained. From an analysis of the underground contours of the Barnsley bed, it is found that its strike lines generally range from N.E.–S.W. or N.W.–S.E., it being difficult to find either a N.–S. or E.–W. strike constant over more than a few miles of country. The greatest structural division of the coalfield basin is by the equivalent of a N.E.–S.W. anticline, of which the southern limb is along the line of the Don faults from Sheffield to Doncaster. North of this line there is some evidence of a syncline with its axis central near Frickley. The inclination of the Barnsley bed is steepest near the outcrop, the measures flattening out when the central line of the syncline is approached. The map indicates the interdependence of underground structure and topographical relief.

On September 10 both morning and afternoon meetings of the Section were required to complete the programme. The morning session commenced by a description by Prof. J. W. Sollas of reconstructions of fossils by serial sections, illustrated by several remarkable models of restorations of a graptolite, a primitive fish, the skull of a reptile from the Karoo, and the skull of *Ichthyosaurus communis*, from Lyme Regis. The last-named was 520 mm. in length, and had been studied in 520 sections taken at equal intervals apart, and revealed in remarkable detail the internal structure of the head. Prof. R. C. Wallace, of Manitoba, described the brine springs of that area, which issue from the Middle and Upper Devonian limestones, and circulate in the Dakota limestone at the base of the Cretaceous, depositing salt at certain dolomitic horizons. The salt flats where the springs reached the surface were devoid of vegetation and studded with ice-carried boulders, granite, gneiss, etc., which have suffered intense chemical disintegration. Ferromagnesian minerals have been most intensely affected. The causes of this special disintegration, as compared with that of sea-water, were discussed. The boulders were partially submerged and films of liquid were maintained on the surface, in contact with atmospheric oxygen. Owing to partial adsorption by colloids an acid residual solution was produced, which is a powerful corrosive agent.

Dr. Albert Wilmore dealt with the Carboniferous limestone zones of N.E. Lancashire, describing the sequence found in the neighbourhood of Clitheroe and the Knoll district. Mr. H. Day referred to observations on a collection of fossils from Treak Cliff and Peakshill, Castleton, and discussed the value of the brachiopods and corals as zonal determinations, when compared with those of the Bristol area. He concluded that any system of zonal indices could be of local value only, and not of general application. Dr. Arthur Vaughan, who was recovering from a serious

illness, dealt with the shift of the western shore-line in England and Wales during the Avonian period. He concluded that a land mass stretching from Wales to Wicklow formed a barrier during the Avonian period between a "N.W. channel," reaching to the Isle of Man and the Lake district, and a "S.W. channel," which was an extended Bristol Channel. This barrier formed the land-crest between these two channels during the whole of Viséan time, and had a dominant trend from Anglesey to Dudley. The whole neck of land which contained the barrier and separated the "channels" shifted steadily southwards as Viséan time proceeded, owing to the advance of the sea on its northern side and its retreat on the south. The remarkable similarity of the Viséan sequence north and south of this barrier indicated free sea communication round its western margin, along which the sea remained persistenly coastal during the period.

Dr. Albert Jowett contributed a preliminary note on the glaciation of the western slopes of the southern Pennines. No striated surfaces of solid rock had been found at high levels, and for detailed information of the ice-movement we had to depend on striations at Salford and Fallowfield, on the distribution of drift at high levels, and on the systems of drainage along the edge of the ice. These indicated a general movement from N.W.–S.E. The first barrier of hills met with on approaching the Pennines from the South Lancashire and Cheshire plain was almost everywhere overridden with ice, which left definite deposits of drift with foreign rocks up to 1360 ft., and scattered erratics up to 1400 ft. This drift had been traced across the main Pennine divide near Chapel-le-Frith (1100 ft.). Great lakes were held up by the ice-barrier some time after it commenced to retreat from the western slope of the Pennines. During early stages of the retreat the drainage from the lakes in and north of the Etherow valley escaped northwards, and ultimately discharged through the Walsden gap into the Calder. When the ice-barrier east of Manchester fell below 600 ft., this drainage followed the course of that south of the Etherow valley and escaped southwards.

The afternoon meeting commenced with a discussion on radio-active problems in geology. Sir E. Rutherford opened the discussion by putting the problem from the point of view of the older geologists, with their comparatively low estimate of the age of the earth, though higher than physicists of those days were inclined to concede. The discovery of radium had greatly modified the position, and the age of the earth, based on evidence of radio-activity, was very much higher than the estimates accepted by geologists. The problem was how to reconcile geological facts with these new physical determinations. Sir Ernest Rutherford was inclined to believe that the larger estimates were nearer correct than the smaller.

Prof. J. Joly faced the problem from the viewpoint of the geologist on the assumption that geologists were agreed on the matter. He made several suggestions which might have the effect of reducing the large numbers derived from the study of radio-active materials.

Prof. Soddy hoped that geologists would not be in any immediate hurry to decide between the geological and radio-active estimates of the age of the earth. Owing to the element of uncertainty about the initial stages of the disintegration and the long periods involved, there was a great *terra incognita*, and the new theory of isotopes made it necessary to take into account many possibilities not thought of a couple of years ago. In addition there was always the possibility that thorium might be a branch of the uranium family, in which case some of the arguments that had been used entirely fell to the ground. While he saw no successful method at present of altering the *general* order of the radio-active estimate, he did not regard it as more than tentative, and there might well be unknown factors of sufficient importance to bring the two methods into closer agreement in the future. Dr. J. H. Teall, Prof. Sollas, and Dr. J. W. Evans continued the discussion.

Prof. C. A. Edwards described the results of experiments producing twinning in metallic crystals. His remarks were illustrated by an interesting series of lantern slides. Dr. J. W. Evans followed with a description of the different methods by which the interference figures of a small mineral in a rock slice could be kept distinct from those of the adjoining minerals. He discussed various methods of using a diaphragm with the Becke combination of lenses, and condemned the common practice of placing the diaphragm for this purpose immediately below the Bertrand lens.

Dr. G. Hickling contributed a paper on the microstructure of coal, illustrated by a series of beautiful lantern slides, showing remarkable success in dealing with very difficult material. He concluded that coal was essentially a "replacement" deposit consisting of an original peat-like mass of vegetable *débris*, in which the substance of the component tissues has been largely or wholly replaced by the liquid decomposition products of other vegetation. The concluding paper was by Mr. Thomas Crook, describing the economic mineral products of Damaraland, S.W. Africa, and emphasising their value. Several research committees were reappointed; and new committees were appointed to investigate rocks of Old Red Sandstone age at Rhynie, Aberdeenshire, and of Lower Carboniferous age at Gullane, Haddingtonshire. The sectional work concluded with a field excursion to Edale and Castleton. The surprise of the week was the magnificent weather, which made a successful meeting also a delightful memory.

W. L. C.

CORRESPONDING SOCIETIES AT THE BRITISH ASSOCIATION.

THE first meeting of the Conference of Delegates was held on September 8, and it was announced that the General Committee of the British Association had altered the titles of officers of the Conference from Chairman and Vice-Chairman to President and Vice-President, thereby giving them the same status as those of the Sections. Sir Thomas Holland delivered his opening address, entitled "The Classification of Scientific Societies," which was printed in NATURE of September 16.

The first subject for discussion was "Local Museums," suggested by the Selborne Society, and introduced by Dr. W. E. Hoyle. He laid it down that the first and fundamental function of a museum was to preserve. Museum officials are nowadays given so much advice about the desirability of making our exhibits æsthetically attractive, of compiling explanatory labels which shall at the same time instruct the specialist and interest the casual visitor, and of catering for school children, that they are, he said, in danger, perhaps, of forgetting that their paramount duty is to see that "neither moth nor rust doth corrupt" and that "thieves do not break through nor steal."

He gave a definition of a local museum, the first duty of which, he maintained, was to preserve the things of interest pertaining to the locality. Then he touched upon the important and delicate question of

the relations which ought to exist between the local museum and the national museum. Difficulties arose when it was required to determine in particular cases what objects were of national importance and should be preserved in a national museum.

After the first function of a local museum had been adequately discharged, Dr. Hoyle thought that if means and opportunities allowed, collections should be provided which gave the visitor a preliminary sketch of some department of knowledge. He alluded to "index" collections, though he thought the term "introductory" collections would be more appropriate. Dr. Hoyle had something to say with regard to the coming into touch of the museum with the educational system of the locality, and he saw nothing out of place in a local museum developing a special subject quite disconnected with the locality if it had the power to do so without interfering with its proper work.

In the discussion which followed, Dr. Bather touched upon principles which should guide local curators in their selection of what should be considered of national and local interest. Type specimens should be placed in museums where they would be well looked after. Moreover, researchers, though they would naturally seek for local objects, such as fossils, in a local museum, ought not to have to look for, say, New Zealand fossils, through all the museums of the British Isles.

Dr. Marie C. Stopes thought that there might be a balance of good in decentralising collections, even of type specimens, for the visiting of local museums brings a stimulus to the local people, and widens and humanises the interests of specialists.

It seemed evident from other remarks that if local museums are to be properly educational, in the general sense of the word, there should be special institutions or special sections of existing museums with their own organisation, so as not to burden curators unduly.

Prof. Geddes directed attention to the survey of Greater London now being carried out by the Architects' War Committee, which deserved the co-operation of museums and natural history societies.

The second meeting was held on Friday, September 10. As a result of the importance of the presidential address, and the interest which had been taken in its suggestions, the vice-president, Mr. William Whitaker, moved a resolution in the following terms:—"That this conference invites the attention of the Corresponding Societies' Committee to the president's opening address, in which suggestions are made for reforming the existing, varied, and unorganised practice of publishing original papers." An outline was given of ways in which this might be done, and the resolution was carried.

The second subject for discussion was "Colour Standards," suggested by the British Mycological Society, and introduced by Mr. J. Ramsbottom. He described and illustrated a number of the schemes which had been formulated with the object of obtaining some uniformity of colour description in the many branches of natural science. Recent attempts at colour standards have each something against their general adoption, and, except for horticulturists, mycologists, and possibly ornithologists, they are much too full. It would seem best to have a well-arranged list of two hundred well-named colours for ordinary use, which colour scheme could be amplified in those branches of science where needed.

In this case, also, a good discussion was aroused, and as it was pointed out that the work of preparing such a series of colour standards for scientific and commercial uses, though of interest to many of the committees of the Association, was not the province of any one of them, a resolution was passed referring the matter to the Corresponding Societies' Committee.

In many ways the Conference of Delegates at Manchester was the most successful that had been held in this country for a considerable time.

Wilfred Mark Webb.

SECTION B.

CHEMISTRY.

Opening Address [1] by Prof. William A. Bone, D.Sc., F.R.S., President of the Section.

This year is, as many of you are doubtless aware, the centenary of Davy's invention of the miner's safety lamp which formed the starting point of his brilliant researches upon flame, in which he disclosed, and brought within the range of experimental inquiry, most of the intricate and baffling problems connected with the fascinating subject of gaseous combustion. Also the ground on which we meet to-day is known to the whole scientific world as the place where, during more than a quarter of a century of continuous investigation, a succession of Manchester chemists, led and inspired by Prof. H. B. Dixon, have devoted themselves to the elucidation of the many problems which Davy's work foreshadowed. Therefore, both in point of time and place, the occasion is singularly appropriate for a review of recent advances in this important field of scientific inquiry.

At the Sheffield meeting of the Association in 1910, I had the honour of presenting to a joint conference of Sections A and B (Physics and Chemistry) a report summarising the then "State of Science in Gaseous Combustion," [2] which gave rise to a keen and stimulating discussion, and was not only printed *in extenso* in the annual reports for that year, but was also widely circulated through the medium of the scientific and technical Press. There is no need, therefore, for me to refer in any detail to the results of researches already dealt with in that report. I can more usefully devote part of the time at my disposal to supplementing it with a review of more recent researches, which have considerably extended our knowledge in many directions.

Gaseous Combustion: Ignition Phenomena.

The first section of my 1910 report was concerned with ignition temperatures and the initial phases of gaseous explosions; and it is in connection with ignition phenomena that subsequent progress has been most marked.

For the ignition of a given explosive mixture, it is necessary that the temperature of its constituents should be raised, at least locally, to a degree at which a mass of gas self-heats itself by combination until it bursts into flame, or, in other words, to a degree at which the chemical action becomes autogenous or self-propelling, so that it quickly spreads throughout the whole mass. This particular degree, or in some cases range, of temperature is commonly spoken of as the ignition-point of the mixture; but in using the expression, certain qualifications should be carefully borne in mind. In the first place, as H. B. Dixon and H. F. Coward showed in 1909,[3] whereas when certain combustible gases—such, for example, as hydrogen and carbon monoxide, the mechanism of the combustion of which is probably of a fairly simple character—and air or oxygen are separately heated in a suitable enclosure before being allowed to mix, the temperature at which ignition occurs lies within a

[1] Abridged by the author.
[2] See *Journal of Gas Lighting*, vol. cxi., p. 648.
[3] *Ibid.*, vol. cvii., p. 323.

very narrow range, which is, within the limits of experimental error, the same for both air and oxygen (*i.e.* in the case of hydrogen it is 580° to 590°, and for carbon monoxide 640° to 658°). On the other hand, in cases where the mechanism of combustion is known to be very complex (*i.e.* hydrocarbons), the ignition range is either fairly wide or else is materially lower in oxygen than in air (or both). Thus—

	In air	In oxygen
Methane	650°–750° ...	556°–700°

The explanation of such behaviour is probably to be sought in the known complexity of the combustion, and the marked tendency for appreciable and fairly rapid interaction between the inflammable gas and oxygen before the actual ignition-point is reached. If, by any means, such preliminary interaction could either be entirely suppressed, or if, on the other hand, it be very rapid in character, the observed "ignition range" would be narrowed, as is actually the case with ethylene (542° to 547° in air, and 500° to 519° in oxygen).

There are two other means by which an explosive mixture may be ignited. One is by adiabatic compression, and the other, and most commonly employed of all, is by the passage of an electric spark. The adiabatic compression of an explosive mixture was originally suggested by Nernst as a means of determining its ignition-point, provided (1) that ignition is not produced locally, while the main temperature of the gas is still far below the true ignition temperature; (2) that the piston of the apparatus does not move appreciably after the gas has been raised to its ignition-point. At the time of my 1910 report, Falk, in America, had applied the method in the case of hydrogen and oxygen mixtures, with results which, in the light of more recent work, would appear to have been misleading or erroneously interpreted. Thus, for instance, he found that of all the mixtures of hydrogen and oxygen, the equimolecular H_2+O_2 mixture has the lowest ignition temperature (514°), from which he concluded that the gases react initially to produce hydrogen peroxide rather than steam. Such a conclusion, which I believe to be erroneous, naturally directed attention to the experimental method involved.

The subject was promptly taken up here, in Manchester, by H. B. Dixon and his co-workers,[4] with the result that much new light has been thrown on the phenomena accompanying ignition. The ratio of the ignition temperature to the initial temperature of the mixture before compression, both expressed in degrees absolute (T_2/T_1), may be calculated from the compression ratio (V_1/V_2) by means of the well-known formula for adiabatic compression:

$$\frac{T_2}{T_1}=\left(\frac{V_1}{V_2}\right)^{\gamma-1}$$

where γ = the ratio of the specific heats at constant pressure and volume, respectively, of the mixture compressed, and which for a mixture of diatomic gases, such as hydrogen and oxygen, is usually taken as 1·40.

Dixon's recent photographic analysis of the appearance of flame when mixtures of carbon bisulphide and oxygen (CS_2+3O_2) are adiabetically compressed, have proved that the flame, starting from a point or layer, always takes an appreciable time to spread through the mixture, and that unless special precautions are taken to arrest the piston at the moment of its attainment of the ignition condition, it may be driven in much further than the minimum distance for ignition.

The real ignition-point, as above defined, is not necessarily synchronous with the actual appearance of the flame. There may be, and usually is, an appreciable "pre-flame" period. Only in the fastest burning mixtures is this period negligible; hence the necessity of artificially stopping the movement of the piston at the beginning of the period—a precaution which Falk seems to have neglected.

According to Dixon and Croft's recent determination by this method of the ignition-points of mixtures containing electrolytic gas, whereas successive additions of hydrogen or nitrogen progressively raise the ignition temperature of the undiluted gas by regular increments, as would be supposed, successive additions of oxygen, on the other hand, lower it, as a glance at the following table will show:—

Ignition Points of Mixtures Containing Electrolytic Gas by Adiabatic Compression.

(H. B. Dixon and J. M. Crofts, 1914.)

Electrolytic Gas, $2H_2+O_2=526°$

$+x\,H_2$	$+x\,N_2$	$+x\,O_2$
x=1 ... 554°	x=1 ... 537°	x= 1 ... 511°
x=2 ... 561°	x=2 ... 549°	x= 7 ... 478°
x=4 ... 602°	x=4 ... 571°	x=15 ... 472°
x=8 ... 676°	x=8 ... 615°	
(526+18 x)°	(526+11 x)°	

The observed raising effects of successive dilutions with hydrogen and nitrogen call for no comment, save that the relatively greater effect of hydrogen as compared with nitrogen may be attributed to its greater thermal conductivity; but the lowering effect of oxygen is indeed puzzling, and its meaning can only be conjectured. Dixon and Crofts have suggested that it may be due either to the formation of some active polymeride of oxygen under the experimental conditions, which seems to me doubtful, or that the concentration of oxygen in some way or other brings about increased ionisation of the combustible gas. This at once raises the larger question of whether or not ignition is a purely thermal problem, as until recently has generally been supposed.

Prof. W. M. Thornton, of Newcastle-upon-Tyne, recently published some very suggestive work on the "Electrical Ignition of Gaseous mixtures,"[5] which, apart from its theoretical interest, has an important bearing on the safety of coal mines where electrical currents are used for signalling and other purposes.

The common belief that any visible spark will ignite a given explosive mixture of gas and air is, of course, quite erroneous; for just as Coward and his coworkers have shown that for a given explosive mixture and sparking arrangement there is a certain limiting pressure of the gaseous mixture below which ignition will not take place, so from Thornton's work it would appear that a definite minimum of circuit energy is required before a given mixture at given pressure can be ignited by a spark. And, moreover, he has stated that the circuit energy required for the spark ignition of a given mixture (say) of methane and air is something like fifty-six times greater with alternating than with continuous current at the same voltage. From this he has argued that the igniting effect cannot be simply thermal, but must be in part at least ionic. This conclusion he further supports with the statement that the igniting power of a unidirectional current is proportional to the current in the case of many gaseous mixtures over an important part of their working range of inflammability.

While there is much that is suggestive in Thornton's work, there is also a good deal which seems

[4] H. B. Dixon, L. Bradshaw, and C. Campbell, Trans. Chem. Soc., 1914, pp. 105, 2027; H. B. Dixon and J. M. Crofts, *ibid.*, p. 2036.

[5] Proc. Roy. Soc., A, vol. xc., 1914, p. 272; vol. xci., 1914, p. 17.

very difficult to interpret from a chemical viewpoint. I here refer more particularly to his later supposition of "stepped ignition," which is based upon certain observed abrupt increases in the minimum igniting current required with condenser discharge sparks as the proportion of combustible gas in the air mixture examined progressively increases. In other words, it is claimed that continuous alteration of the proportions of gas and air in an explosive mixture is, or may be, accompanied by discontinuous alterations in the spark energy required for ignition. I must confess that, after careful examination of the published curves, I am quite at a loss to give them any chemical interpretation, and to being somewhat sceptical about the supposed "stepped ignition." A repetition and extension of Prof. Thornton's experiments would be most valuable as a means to a better understanding of the conditions of spark ignition.

Influence of Electrons upon Combustion.

During the discussion upon my 1910 report, Sir J. J. Thomson reminded us chemists that combustion is concerned, not only with atoms and molecules, but also with electrons moving with very high velocities. They might be a fact of prime importance in such intensive forms of gaseous combustion as are realised in contact with hot or incandescent surfaces, as also in the explosion wave. It is well known, of course, that incandescent surfaces emit enormous streams of electrons travelling with high velocities, and the actions of such surfaces may be due to the formation of layers of electrified gas in which chemical changes proceed with extraordinarily high velocities. Again, the rapidity of combustion in the explosion wave might, he thought, conceivably be due to the molecules in the act of combining sending out electrons with exceedingly high velocities, which precede the explosion wave and prepare the way for it by ionising the gas.

With regard to this interpretation of the action of surfaces, Mr. Harold Hartley carried out a promising series of experiments in my laboratory at Leeds University upon the combination of hydrogen and oxygen in contact with a gold surface, which lend some support to the idea. But they require further extension before it can be considered as finally proved. It is my intention in the near future to resume the systematic investigation of the matter as rapidly as circumstances permit; but the experimental difficulties are formidable, and the mere chemist working by himself may easily be misled. We badly need the active co-operation of physicists in elucidating the supposed *rôle* of electrons in combustion.

Prof. H. B. Dixon and his pupils have, at Sir J. J. Thomson's suggestion, recently tested the idea as applied to the explosion wave, with, however, negative results.[6] It is known, of course, that the motion of the ions can be stopped at once by means of a transverse magnetic field, in which they curl up, and are caused to revolve in small circles; and the question which Prof. Dixon decided to put to the test of experiment was whether the damping of the electronic velocities in a powerful magnetic field would have any appreciable effect either upon the initial phase of an explosion or upon the high velocity of detonation. But though he employed a very intense magnetic field produced by some powerful magnets specially constructed by Sir Ernest Rutherford for the deflection of electrons of high velocity, no appreciable effect was observed upon the character or velocity of the flame with any gas mixture at any stage of the explosion. And inasmuch as the high constant velocity of the explosion wave can be entirely accounted for on the theory of a compression wave liberating the chemical energy as it passes through the gases, there seem as yet to be no experimental grounds for attributing it to the ionising action of electrons.

The Initial Period of "Uniform Movement" or "Inflammation" of Flame through Inflammable Mixtures, and Limits of Inflammability.

Mallard and Le Chatelier, in their classical researches upon the combustion of explosive mixtures, discovered that the propagation of flame, when such a mixture is ignited in a horizontal tube, differs according as whether the ignition occurs near the open or closed end of the tube. In the first case, the flame proceeded for some distance down the tube at a practically uniform and fairly slow velocity, corresponding to the true rate of propagation "by conduction." This period of uniform movement is succeeded by an irregular oscillatory period, in which the flame swings backwards and forwards with increasing amplitudes, finally either dying out altogether or else giving rise to detonation. With certain oxygen mixtures, the initial period of uniform slow velocity was shorter, and appeared to be abruptly succeeded by detonation without the intervention of any oscillatory period. When, however, such mixtures were ignited near the closed end of a horizontal tube, the forward movement of the flame was continuously accelerated from the beginning, under the influence of reflected compression waves, until detonation was set up. Such, in general, was the sequence of the phenomena that were observed by these distinguished French investigators.

They proceeded to determine experimentally the velocities of the uniform slow movement of the flame in the case of a number of air and combustible gas mixtures, and plotting their results (in cms. per sec.) as ordinates against percentages of inflammable gas as abscissæ, they obtained "curves" which were in each case formed of two inclined straight lines converging upwards to a point which represented the composition and flame velocity of the most explosive mixture. And they concluded that the points at which the downward production of the two lines met the zero velocity line would define the upper and lower limits of inflammability for the particular series of gas-air mixtures. Thus the curve they obtain for methane-air mixtures showed a maximum velocity of 61 cms. per second for a mixture containing about 12·2 per cent. of methane, with lower and upper limits corresponding to 5·6 and 16·7 per cent. of methane respectively.

An exact knowledge of the velocities of flame propagation during this initial period of uniform slow movement, as well as of the limits of inflammability for mixtures of various combustible gases and air, is very important from a practical point of view. Makers of apparatus for burning explosive mixtures of gas and air want to know the speed of flame propagation through such mixtures, not only at ordinary temperatures and pressures, but also when the mixtures are heated and used at higher pressures. Also, it would be important to know whether or not, in the case of a complex mixture of various combustible gases and air, when complete composition can be determined by analysis (as, for example, coal gas and air), the velocity of flame propagation can be calculated from the known velocities for its single components. Unfortunately, although more than thirty years have elapsed since Mallard and Le Chatelier's work was published, the necessary data are still wanting to answer such questions; and anyone who will systematically tackle the problem and carefully work

it out in detail will be doing a real service to the gas-using industry.

An accurate knowledge of the behaviour of methane-air mixtures under known variations of conditions is of prime importance from the point of view of the safety of coal mines, and it is rightly occupying the attention of my friend and former collaborator, Dr. R. V. Wheeler, at the Home Office Experimental Station at Eskmeals. From papers which he has already published, as well as from some unpublished results which he has very kindly permitted me to refer to in this address, it is now possible to correct certain errors in Mallard and Le Chatelier's results, and to arrive at a clear view of the phenomena as a whole.

In the first place, it would appear that the initial "uniform movement" of flame in a gaseous explosion, or, in other words, propagation of the flame from layer to layer by conduction only (as defined by Le Chatelier) is a limited phenomenon, and is only obtained in tubes of somewhat small diameter—wide enough, however, to prevent appreciable cooling of the flame, but narrow enough to suppress the influence of convection currents. Moreover, ignition must be either at or within one or two centimetres of the end of the tube; otherwise—particularly with the more rapidly moving flames—vibrations may be set up right from the beginning.

While all methane-air mixtures develop an initial uniform slow flame-movement period when ignited at, or near, the open end of a horizontal tube, both its linear duration as well as the flame velocity are not, according to private information which Dr. Wheeler has sent me, independent of the dimensions of the tube. The speed of flame increases with the diameter of the tube; and the linear duration of the uniform period increases with both the diameter and length of the tube up to a certain maximum, after which increased length probably makes no appreciable difference. Also, for the same tube, it varies with the proportion of methane in the explosive mixture—being greater as the speed of the flame diminishes, until with the two "limiting" explosive mixtures it appears to last almost indefinitely.

Dr. Wheeler's recent re-determination of the velocities of the flame movement during this initial uniform period for mixtures of methane and air in varying proportions within the limits of inflammability, has revealed serious errors in Mallard and Le Chatelier's original results for horizontal tubes of the same diameter as those which Dr. Wheeler has employed. Moreover, Mallard and Le Chatelier's method of determining the composition of the upper and lower limits of inflammability by extrapolation from their curves has been proved to be unwarranted. Dr. Wheeler considers the length of the tubes used by Mallard and Le Chatelier (1 metre only) was insufficient to ensure that the speed measurements of the initial uniform flame-movement period were unaffected by the subsequent "vibratory period." Also, the methane used by them, prepared as it was from sodium acetate, would obviously be impure. According to Wheeler, the limits of inflammability for horizontal propagation of flame in methane-air mixtures, at atmospheric temperature and pressure, correspond to 5·4 and 14·3 per cent. methane contents, respectively.

Messrs. Burgess and Wheeler have recently determined the limits of inflammability of methane when mixed, at atmospheric temperature and pressure, with "atmospheres" of oxygen and nitrogen containing less oxygen than ordinary air. From their results (see below) it would appear that, as the oxygen content of the atmosphere is reduced, the limits of inflammability are narrowed until they coincide when the oxygen content falls below 13·3 per cent., which means that an atmosphere containing 13·3 or less per cent. of oxygen is truly extinctive for a methane flame at ordinary pressures.

Atmosphere		Methane, per cent.	
Oxygen	Nitrogen	Lower limit	Higher limit
20·90	79·10	5·60	14·82
17·00	83·00	5·80	10·55
15·82	84·18	5·83	8·96
14·86	85·14	6·15	8·36
13·90	86·10	6·35	7·26
13·45	86·55	6·50	6·70

Behaviour of Weak Mixtures of Gases and Air.

My review of this part of the subject would be incomplete without a reference to some interesting observations which have been made by Dr. H. F. Coward and co-workers at the Manchester School of Technology, upon the behaviour of weak mixtures of various inflammable gases and air, at, or just below, the lower limit of inflammability in each case.[7] Their principal experiments were carried out in a rectangular box of 30 cm. square section and 1·8 metres length, with two opposite sides of wood, and the other two of plate glass. The box was placed in an upright position, the bottom being water-sealed and the top closed, with a suitable igniting device placed near the bottom. They have shown that caps or vortex rings of flame may be projected for some distance upwards from the source of ignition—sometimes apparently for an indefinite distance—without igniting the whole of the combustible mixture. In such mixtures there may be an indefinite upward slow propagation of flame, together with incompleteness of combustion, much of the combustible mixture remaining unburnt, and the question very naturally arises as to how the term "inflammability" should be scientifically defined. Dr. Coward has argued, with some force, that a gaseous mixture should not be termed "inflammable" at a given temperature and pressure, unless it will propagate flame indefinitely—the unburnt portion being maintained at that temperature and pressure. Inflammability thus defined would be a function of the temperature, pressure, and composition of a particular mixture only, and would be independent of the shape and size of the containing vessel; and, provided that it is kept in mind that for each particular mixture at a given temperature and pressure a certain minimum igniting energy and intensity is requisite, I am inclined to agree with the definiton. Also, there is a possibility that in a mixture just at, or very near, one or other of the limits of inflammability, flame may be propagated upwards, but not downwards.

From his experiments, Dr. Coward has assigned the following as the lower limits of inflammability of hydrogen, methane, and carbon monoxide respectively, in air at atmospheric temperature and pressure:—

	Per cent.
Hydrogen	4·1
Methane	5·3[8]
Carbon monoxide	12·6

Recent Investigation upon the Combustion of Hydrocarbons and the Relative Affinities of Methane, Hydrogen, and Carbon Monoxide respectively for Oxygen in Flames.

(This part of the address, which was read as a separate paper, reviewed the principal results of an investigation by Prof. Bone and collaborators on

7 Trans. Chem. Soc., 1914, vol. cv., p. 1859.

8 Too much stress need not be laid upon the difference between this number and the 5·6 per cent. given by Dr. Wheeler (*loc. cit.*) because Dr. Coward himself admits that the flames of mixtures containing from 5·3 to 5·6 per cent. of methane are very sensitive to shock; while a 5·6 per cent. mixture will always propagate flame indefinitely, even when there is a moderate disturbance. The conditions must be exceedingly tranquil to prevent extinction in the other cases.

"Gaseous Combustion at High Pressures," recently published *in extenso* in Phil. Trans. Roy. Soc., A, vol. ccxv. (1915), pp. 275 to 318.)

Fuel Economy and the Proper Utilisation of Coal.

Leaving now the scientific aspects of flame and combustion, I wish to say a few words as a technologist upon the great national importance of a more adequate scientific control of fuel consumption and the utilisation of coal generally, with special reference to the situation created by this terrible and ruinous European conflict. And my remarks will be addressed in part to my chemical friends and colleagues, who are primarily interested in scientific research and its industrial applications, and in part also to the commercial and manufacturing community which is chiefly interested in the financial results of such scientific activity.

Notwithstanding the fact that we are raising annually in the United Kingdom—according to the official estimate for 1913—287 million tons of coal, of which 189 million tons (or, say, 4 tons per head of the population) were consumed at home, more or less wastefully, it is indeed surprising how little has been done, or is being done, by the scientific community to impress upon the Government and the public generally the importance of establishing some systematic control or investigation of fuel consumptions in all large industrial areas. Deputations have waited upon the Government about the question of reviving our languishing coal-tar colour industry; so that in future we may be independent of Germany for the supply of the 2,000,000*l*. of dye-stuffs required by our textile industries; and already a State-aided organisation, with an advisory scientific committee, has sprung into existence to achieve this desirable result. But no organised body of men of science, so far as I know, has ever thought it important, or worth while, to take an active interest in the vastly greater subject of fuel economy and the proper utilisation of coal, upon which the dyeing industry depends for its raw material.

It is unnecessary for me to remind you that the contending armies in this Armageddon of the nations depend upon certain distillation products of coal for their supplies of high explosives; and there is little doubt in my mind but that Germany's violation of the neutrality of Belgium, and her subsequent seizure of that country and of a large tract of northern France, had more than a purely political or strategic significance. She, doubtless, wanted also to seize for herself (and at the same time to deprive her enemies of) coalfields lying just beyond her own borders, which are capable of furnishing abundant supplies of coal admirably adapted for yielding the raw materials for the manufacture of high explosives. A country in which all metallurgical coke has for years past been manufactured under chemical supervision in bye-product coking-ovens, with recovery of ammonia, tar, and benzol, and in which the wasteful beehive coking-ovens have long ago ceased to exist, was scarcely likely to overlook the military importance of the Belgian coalfield with its many bye-product coking-plants. And, moreover, but for German commercial acumen and enterprise, during many years past, our own bye-product industry would not have attained even to its present respectable dimensions. Certainly it owes very little to the interest or attention of British chemists, most of whom are, unfortunately, but little aware of its circumstances and conditions, and seem to care even less for its particular problems. And yet, in proportion to the capital outlaid upon it, it is one of the most profitable of all our chemical industries, coal-tar colours not excepted.

Fuel economy, and the proper utilisation of coal, whether in connection with manufacturing operations or domestic heating, will become one of the most important national questions during the trying years that will follow hard upon this war, because of all directions in which national economy can be most healthfully and advantageously exercised, this is perhaps the most obvious and prolific. For it is tolerably certain that, with an efficient and systematic public supervision of fuel consumption, we ought to be able, even with existing appliances, to save many millions of pounds of our annual coal bill, and with improved appliances still more millions—a saving which would in the long run redeem a considerable amount of the war loan which has been much more easily raised than it will be repaid.

Now, I fear that not only are chemists for the most part lamentably ignorant of the nature of coal, and of modern fuel technology, but they have been for many years past so indifferent about such questions that they have been content to leave them almost entirely to engineers, who, as a body, are notoriously deficient in chemical sense and experience. The engineer has, indeed, not usurped the place of the chemist, but has had to do his best to fill the position long since abdicated by the chemist.

This, indeed, seems strange when we remember that the foundations of modern chemistry were deeply laid by investigators who were, above all things, "fire-worshippers." But, judging from most chemical text-books, nearly all that the modern student of chemistry is taught in our academies about combustion was known to Lavoisier; and I question whether in the majority of our university laboratories any investigation on coal or combustion is ever undertaken. And yet the subject is full of most fascinating and fundamental theoretical problems—for the most part unsolved—and the nation consumes every week as much coal as could be exchanged for the whole quantity of aniline dyes used by its textile industries in a year.

Moreover, such advances as have been made during recent years—and they are by no means inconsiderable—have nearly all been in the direction of the wider applications of gaseous fuels. Yet in how many of our university laboratories is even gas analysis taught, or how many of our schools of chemistry provide systematic courses in the chemistry and manipulation of gases, without which no professional training of industrial chemists, however much "research work" it may include, ought to be considered satisfactory? It is my opinion that this important branch of our chemical craft and science has not, for many years past, been accorded its proper place and share of attention in the ordinary curriculum of the majority of our academic institutions.

Of the 189 million tons of coal consumed in the United Kingdom in the year 1913, about 40 million tons, or, say, approximately one-fifth of the whole, were carbonised either in gas works, primarily for the manufacture of towns' gas, or in coke-ovens for the manufacture of metallurgical coke—in practically equal proportions. Two-thirds of the latter was carbonised in bye-product recovery plants; the remainder in the old wasteful beehive ovens. So that, roughly speaking, we have—

Total coal carbonised=40 million tons				
In gas-works		In bye-product coke ovens		In beehive coke ovens
20	...	13·5	...	6·5

At present there are 8297 bye-product coke-ovens built in this country, of which 6678 are fitted with benzol recovery arrangements, capable of producing something like 10 million tons of coke per annum.

The yields of the various bye-products obtainable on such coke-oven installations naturally vary with the locality and character of the coal seam; but they probably average somewhat as follows—expressed as percentages on dry coal carbonised:—

District	Ammonium sulphate	Tar.	Benzol and toluol as finished products
Durham ...	0·9 to 1·45	2·5 to 4·5	0·6 to 1·0
Yorkshire ...	1·3 to 1·5	3·5 to 5·0	0·9 to 1·1
Derbyshire ...	1·3 to 1·6	3·5 to 5·0	0·9 to 1·1
Scotland ...	1·4 to 1·6	3·5 to 5·0	0·9 to 1·1
South Wales ...	0·9 to 1·1	2·0 to 3·5	0·6 to 0·75

Or, to put the matter a little differently, each ton of dry coal carbonised yields from 20 to 35 lb. of ammonium sulphate, from 56 to 112 lb. of tar, and from 2 to 3½ gallons of crude benzol, etc.—according to the locality. About 65 to 70 per cent. of the crude benzol is obtained as finished products—benzene, toluene, solvent and heavy naphthas.

How rapid has been the development of the bye-product coking industry in this country during recent years may be judged from the following official returns of the quantities of ammonium sulphate annually made by such plants, as compared with the corresponding quantities produced in gas-works.

Year	Tons of ammonium sulphate produced in: Bye-product coke-oven plants	Gas-works
1903 ...	... 17,435	... 149,489
1908 ...	... 64,227	... 165,218
1913 ...	... 133,816	... 182,180

In the natural course of events, the final disappearance of the wasteful beehive coking-ovens from this country is now only a matter of a few years; but I venture to suggest that public interest would justify the Government fixing, by law, a reasonable time-limit beyond which no beehive coke-oven would be allowed to remain in operation, except by express sanction of the State, and then only on special circumstances being proved.

There is also much need of a better and more systematic chemical control, in the public interest, of bye-product coking plants. At present, in far too many cases, the chemists employed in coke-oven laboratories are men who have practically no chemical training other than that obtained in evening classes. And, with few exceptions, the chemist, however competent he may be, is entirely subordinated to the directing engineer, and regarded as a mere routine analyst. I can say, from personal knowledge, that plants which are managed and controlled by experienced chemists of broad training, combined with force of character, yield much better results than those which are controlled by men without such qualifications.

And even in this crisis when so much depends on plants working, not only at their maximum output capacities, but also, chemically speaking, under conditions calculated to ensure the highest yields of benzol and toluol, with a proper selection of coal, I doubt whether the measures which have been taken to advise and supervise the coke-oven industry are really adequate from the point of view of chemical control. I do know, for instance, that the experience and resources of the majority of our university departments of applied chemistry which specialise on fuel technology and cognate matters have not been as fully utilised as they might have been in this connection. I cannot for one moment imagine a similar state of things being permitted in Germany, where we may be sure that nothing is being left undone in the way of fully utilising all the available expert chemical and engineering knowledge which can be brought to bear on this important aspect of war munitions; and I venture to say that, whatever may be the case in this country, in Germany at least the staff and resources of no publicly maintained department of fuel technology will not be fully employed on war problems.

The coal-gas industry, which deals with some twenty million tons of coal per annum, has, especially within recent years, shown a growing appreciation of the aid of chemical science, in regard not only to the actual manufacture, but also to the domestic and industrial uses of coal gas. The endowment by the industry, in 1910, of a special chair at the Leeds University, in memory of the late Sir George Livesey (of which I had the honour and pleasure of being the first occupant), was a sure sign of the faith of its leaders in the value of scientific research into its special problems; and, from personal knowledge and intercourse with gas engineers, I can assure my chemical colleagues that any serious interest taken by scientific chemists in these problems, or in training men to tackle them, will be welcomed by the industry, no matter from what quarter such help or interest may come. For although the carbonisation of coal in gasworks is efficiently carried out, no one in the industry supposes that finality has been reached, or that existing methods and conditions cannot be improved under better chemical control.

And, moreover, the gas industry has just recently given a striking example of the public benefit which may accrue from the whole-hearted co-operation of the chemist and engineer in the new nickel-catalytic process for the removal of carbon bisulphide from coal gas, which has been worked out, and brought to a successful issue, by the combined skill and efforts of Mr. Charles Carpenter, Mr. W. Doig Gibb, and Mr. E. V. Evans, of the South Metropolitan Gas Company. They have shown that the sulphur content (as CS_2) of London coal gas can be reduced on a large scale, in regular day-to-day working, from nearly 40 to about 8 grains per 100 cubic ft., without in any way deteriorating the quality of the gas, at a cost (including interest and depreciation) of 0·299*d*. per 1000 cubic ft. Such a striking success was, as Mr. Carpenter acknowledges, only achieved "because of the unrestricted and unreserved collaboration of the chemist and the engineer." Incidentally, the gas industry is to be congratulated on this tacit abandonment of the old contention that coal gas was either none the worse for the presence in it of a certain amount of sulphur compound, or (alternatively), if worse, that a minute amount of sulphur dioxide in the atmosphere of a living room is so rapidly absorbed by the ceiling that its harmful effects are nullified.

As the outcome largely of the work of the Joint Committee appointed in 1907 by the Institution of Gas Engineers and the University of Leeds (of which I was a member) to investigate gas-fire problems, the manufacturers of these appliances have paid much more attention than formerly to the scientific aspects of construction, so far as to ensure the best combination of radiant and ventilating effects, and nearly all the larger firms have now their scientific staffs busily employed in making further advances. Prominent among the pioneers in scientific gas-fire construction has been Mr. H. James Yates, who will to-morrow enlighten you as to some of the most recent improvements. I can, however, from personal knowledge testify to the enterprise shown by most of the leading manufacturers, and that their combined efforts have resulted in a very efficient and perfectly hygienic

domestic gas-fire. A committee appointed by the Institution of Gas Engineers, upon which scientific men are largely represented, is now considering the adoption of a standard method of testing the radiant efficiencies of gas-fires. Thus no one can say that the gas industry is not making every effort to put its affairs upon a thoroughly scientific basis.

Passing on to the metallurgical and allied industries (who, of course, are large consumers of fuel), there is much here to be done in improving the construction and operation of furnaces in order to check the waste of fuel. But of these details there is no time to treat; and one instance of the possibilities of very large economies as the result of scientific control must suffice.

It is perhaps common knowledge that the most economical arrangement of plant for the manufacture of iron and steel is one in which bye-product coke-ovens, blast-furnaces, steel furnaces, and rolling mills are brought together on one site and under one organising direction, so that the surplus gases from the coke-ovens and blast-furnaces may be utilised to the fullest extent. My relative, Mr. T. C. Hutchinson, of the Skinningrove Iron Company, who has devoted many years of anxious thought and practical study to this important problem, ventured some few years ago to predict that—with the most approved type and arrangement of plant, working under strict scientific control by competent chemists—it would soon be possible to make finished steel rails or girders from Cleveland ironstone with no further consumption of coal than is charged into the bye-product coke-ovens for the production of the coke required for the blast-furnace, and all subsequent experience at Skinningrove has fully demonstrated that his prophecy can be fulfilled in everyday practice. Of course, it means a constant watchful control by a well-paid and competent scientific staff under efficient leadership, and in Mr. E. Bury—an old Owens College student, trained in an atmosphere of "gas and combustion"—we have found the very man for the work.

It is perhaps unnecessary, even had time permitted, for me to multiply instances of possible economies in other important directions—such, for instance, as power production and the heating of domestic apartments. There is probably no direction in which equally good results would not accrue with proper scientific application and control as those already cited as having been reached in the direction of carbonisation, or in the iron and steel industry. To-morrow we are to discuss the important subject of smoke prevention, in which many Manchester public men are showing an active interest, so that there will be some further opportunity of referring to the matter.

But may I, in conclusion, appeal in all seriousness to chemists and scientific men generally to take up this important matter effectively as a public duty at this crisis in the country's affairs? I would suggest that the Government be memorialised with a view to the establishment of a central organisation for the supervision of fuel consumption and the utilisation of coal somewhat on the lines of the existing alkali works inspection, which has been so beneficial to chemical industry. And in connection with such an organisation there might be undertaken a much needed systematic chemical survey of British coal-fields, as well as experimental trial of new inventions for fuel economies. There would certainly be no lack of important work for such a properly organised department of the State, and there can be no doubt at all that the results of its activities would be, not only a very large direct saving in our colossal annual coal bill, but also a purer atmosphere and healthier conditions generally in all our large industrial areas.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—In his valedictory address to the Senate, the retiring Vice-Chancellor, Dr. M. R. James, the provost of King's College, stated that the University has shrunk to less than one-third of its former numbers; no fewer than 10,000 Cambridge men have entered the military and naval services. The Rev. T. C. Fitzpatrick, president of Queens' College, was elected Vice-Chancellor for the ensuing year. The Quick professorship of biology is vacant, as the period of three years for which Dr. G. H. F. Nuttall was appointed has now ended.

ALTHOUGH much of the best glass used in England is of English manufacture, large quantities of glass, principally of the cheaper types, have been for some years imported. Cheaper labour, cheaper transport, and the scarcity of technically trained managers and chemists, together with the prevalence of "rule-of-thumb" methods, have been the determining factors. The manufacture of fine glass requires a peculiar combination of engineering, physical, and chemical knowledge and training, and the chemical knowledge is not usually obtainable in university or technical college courses, because of the specialised nature of the subjects and the difficulties which arise in translating laboratory experiments into practice on a manufacturing scale. To meet these difficulties, the University of Sheffield has established a department of glass manufacture and technology, and has instituted special technological courses. A syllabus of special lectures and laboratory work has been issued with details of a projected full-time three years' course. The announcement indicates the variety of scientific and technical work which is essential to a good training in glass manufacture, and includes, *e.g.*, the chemistry of the materials, the glasses and pots, the fuel used, the furnaces, the temperatures at which they work, variations in the methods of melting, chemical actions in the process of melting, methods of working the glass, such as rolling, pressing, and blowing, grinding and cutting, and the machinery and appliances incidental to all these operations. The success of these courses will necessarily depend on the co-ordination of the lectures and the laboratory practice with larger scale experimental work; but the University of Sheffield, with its experience of similar problems in the metallurgical department, should be well qualified to deal with these difficult problems. Their successful solution should be of material assistance to a very important and growing branch of British industry which it is particularly essential to encourage as much as possible at the present time.

THE third war programme in connection with the Chadwick Public Lectures dealing with the last quarter of the present year has now been published. Prof. D. Noel Paton is giving a course of three lectures on "Food in War Time" at the Hampstead Central Library, Finchley Road, London, N.W. The first lecture was given on Monday last, and the others will be given on the two succeeding Mondays, at 8.15 p.m. Dr. R. O. Moon, physician to the Serbian Isolation Hospital at Skoplje (Uskub), will lecture on "Typhus in Serbia," at the Royal Society of Medicine, 1 Wimpole Street, Cavendish Square, London, W., at 5.15 p.m. on October 20 and 29, and on November 3. On November 10, at 8.15 p.m., Mr. A. Saxon Snell will lecture on "Emergency Military Hospital Construction" at the Royal Institute of British Architects, Conduit Street, London, W. On November 17, at 8.15 p.m. Mr. W. E. Riley will lecture on "Some Con-

clusions on Housing our Workers," at the Royal Sanitary Institute, 90 Buckingham Palace Road, London, S.W. The admission to all lectures is free.

THE calendar for the current session of Armstrong College, Newcastle-upon-Tyne, one of the constituent colleges of the University of Durham, is now available. Since August, 1914, the buildings of the college have been in the occupation of the War Office, and the various departments of the college are housed temporarily in different buildings throughout the city. The arrangements for the session follow the general lines of previous years. Complete courses of study leading up to degrees in pure and applied science have been provided. Students who wish to graduate in applied science may take up one of the following branches: general mechanical, marine, civil, or electrical engineering, naval architecture, mining, and metallurgy. Such a degree is accepted by the Institution of Civil Engineers in lieu of their examination for associate membership, and by other corporations. Courses are also provided in preparation for degrees in commerce. A gratifying characteristic of the work done in the college is the active co-operation of employers of labour in the district, who have made it easy for students to obtain experience of workshop conditions during or after their college course.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 27.—M. Ed. Perrier in the chair.—Paul **Appell**: A second form of Θ functions of the fourth degree.—Henry Le **Chatelier** and Jules **Lemoine**: The heterogeneity of steels. An account of the application of an etching reagent proposed by Stead (methyl alcoholic solution of cupric and magnesium chlorides containing hydrochloric acid), with details of the proportions found to give the best results. Nine reproductions of microphotographs accompany the paper.—J. **Haag**: A system of differential formulæ concerning the elements of a projectile submitted to a quadratic resistance of air.—Charles **Rabut**: The calculation of the strength of a beam reinforced with metal bands.—P. **Vaillant**: The laws of flow of liquids in drops. The weight of a drop from a given orifice depends on the number of drops per second. It is proved that the weight of a drop is a parabolic function of the frequency of fall, and experimental data are given in support of this.—P. W. Stuart **Menteath**: The Permian of the western Pyrenees.—Jules **Welsch**: The Pliocene lignites of Bidart, Lower Pyrenees. South of Biarritz there are deposits of lignite the age of which is near to the Middle Pliocene.—R. **Chudeau**: Rain and vapour pressure in western and equatorial Africa.—J. **Bergonié**: A new method of physical treatment of the after results of wounds: pneumatic pulsatory massage. A detailed description of the mode of application of mechanical massage to the treatment of masses of cicatricial tissue. Particulars of the results obtained will be published later.—P. **Portier**: The resistance of certain races of *B. subtilis* arising from insects to chemical reagents. The organisms, isolated from the larva of *Tenebrio molitor* and the chrysalis of *Myeloïs cribrella,* prove to survive very drastic treatment, including 50 hours with 5 per cent. phenol, 25 hours with 20 per cent. formaldehyde, 95 per cent. alcohol more than fourteen months, boiling chloroform, and other reagents. This resistance to chemical reagents is greater than any hitherto observed, and has a direct bearing on the problem of sterilisation of instruments and bandages.—J. **Wolff** and Mlle. Nadia **Rouchelmann**: The properties of a chromogen universally distributed in plants.—A. de la Baume **Pluvinel**: The use of Hughes's induction balance for the detection of projectiles in the wounded.

BEAUTY AND DESIGN IN NATURE.

(1) *Genetic Theory of Reality: being the Outcome of Genetic Logic as Issuing in the Æsthetic Theory of Reality called Pancalism.* With an extended glossary of terms. By Dr. J. M. Baldwin. Pp. xvii+335. (New York and London: G. P. Putnam's Sons, 1915.) 7*s.* 6*d.* net.

(2) *The Natural Theology of Evolution.* By J. N. Shearman. Pp. xv+288. (London: George Allen and Unwin, Ltd., n.d.) 10*s.* 6*d.* net.

(1) THIS book cannot be adequately reviewed without embarking more or less on an examination of the distinguished author's whole system as largely presented in his earlier monumental works. Moreover, being concerned with technical philosophy—though a philosophy which accepts and includes science—its appeal is primarily to readers other than those of this journal. It will suffice, therefore, to indicate briefly its scope and purport. The essence of the pancalistic doctrine is its emphasis on beauty. Science tells us what is true; that is science's prerogative. But the universe has beauty and goodness as well as truth. How reconcile and unify? The pancalistic answer is that the good and the true is so because it is beautiful. The final court of appeal is æsthetic. Nothing can be true without being beautiful, nor anything that is in any high sense good. The ascription of beauty, a reasoned, criticised, thought-out ascription of æsthetic quality, is the final form of our thought about nature, man, the world, the all. The volume under notice is an unfolding of this idea, dealing with the aspects of morphology, interpretation, religion (mysticism), and logic.

(2) An excellently written but somewhat diffuse restatement of Paley's argument for design. The author points out that the work of Darwin and his successors does not rule out design; it only requires the supposition that the designing mind works slowly, experimenting through many ages. As to those variations which have turned out failures—the flying reptiles and other extinct creatures of earlier periods—the author makes the suggestion that the direction of variation may to some extent be deputed by God to angels, in the same way as free-will and power is granted to man; and that these failures are the experiments of the angel-subordinates. But the author is not in the least a crank, and he puts forward this fresh and interesting hypothesis (which some would call fantastic) as a speculation only. His main point is that though the Darwinian natural selection is a true cause of change in species, the variations which tend to progress and greater complexity cannot be attributed to chance. They are evidence of a guiding mind which sees and knows before it produces on the material plane.

This, and the accompanying question of what we mean by "chance," is an extremely thorny problem, as the author indeed recognises. His treatment of it is lucid, sincere, and able, whether readers fully agree with it or not. Certainly there is a greater tendency among men of science at the present day to accept a philosophy of Platonic or idealistic type—which looks on Mind as the *prius,* and the material world a manifestation thereof—than at any time since modern scientific method appeared; and to many this very interesting volume will be welcome and useful. It deserves to be widely read.

LIME-SAND BRICKS AND ALLIED PRODUCTS.

Bricks and Artificial Stones of Non-plastic Materials: their Manufacture and Uses. By A. B. Searle. Pp. vi+149. (London: J. and A. Churchill, 1915.) Price 8*s.* 6*d.* net.

AS intimated by the author in the preface, this book is intended: "(*a*) to supply reliable and unbiased information to those firms and individuals who contemplate making or buying bricks and artificial stones from non-plastic materials; (*b*) to assist manufacturers in solving the problems which occur in the course of their work, to enable them to remedy defects and to avoid other technical difficulties." In proceeding to carry out these objects, Mr. Searle treats in some detail the modes of production and uses of lime-sand bricks, clinker bricks, slag bricks, bricks made of crushed rock, concrete bricks and blocks, and various types of artificial stone, etc. As he points out, these products can often be made advantageously in districts where the manufacture of burnt bricks and tiles would be impracticable. Thus in some places the absence of suitable clay, or the want of a readily available supply of coal, would render any attempt to make bricks unprofitable; whilst, on the other hand, the presence in such a district of abundant deposits of sand might make the manufacture of lime-sand bricks perfectly feasible from a commercial viewpoint. It is even practicable in some cases for the two classes of products to be made side by side, the sand frequently found overlying the brick clays being beneficially utilised for the production of lime-sand bricks instead of being simply put away as so much waste material of no value.

A considerable amount of attention and space is devoted to a description of the raw materials,

with their favourable and unfavourable characteristics, methods of preparing and mixing the ingredients (including some brief historical notices), the process of pressing, and the final process of hardening. The subjects of cost, of manufacture, and defects are dealt with in special chapters, as are also the physical properties of the products. The work is embellished with numerous illustrations depicting machinery and appliances suitable for properly carrying out the different kinds of operations.

Much of what is contained in the volume is based partly on the author's personal experiences, and partly on such experiences of other people as have come under his notice. This is in itself a highly commendable feature, but the author's confidently expressed opinions, assuming them to be well-founded, would lose none of their weight if the experimental data on which they are based were set forth more frequently than is the case.

There are a number of misprints, some of them trivial, but several may give rise to much doubt and perplexity. Apart from mere misprints, there are some loosely worded statements which would scarcely be expected from such an experienced writer as Mr. Searle appears to be, judging from the number of his published works. Thus, near the bottom of page 26, we are told that "the three essential ingredients—aggregate, lime, and water—*must be:* (1) *Ground* to the requisite fineness and graded (if necessary). (2) *The proper proportion* of each must be weighed or measured. (3) *Mixed* to form a homogeneous mass in which the lime is fully hydrated." The italics here are, of course, not the author's. Comment is scarcely necessary. It is not suggested that the meaning is obscure, but in quasi-scientific works on technical subjects there should be no flagrant flouting of grammatical rules. On page 82, line 18, 7 per cent. is mentioned instead of 0·7 per cent. There seems no valid reason for the spelling, in some of the later chapters, of "absorbtion" instead of the more orthodox "absorption." A curious mistake occurs at the bottom of the table on page 120, where the "cost of manufacture" of "cement-sand bricks" is stated to be "1 month." In the last sentence of the second paragraph on page 10, owing presumably to displacement of a comma, an absurd statement is made. It is true that the real meaning is rendered clear in the following paragraph, but a practised writer ought surely to guard against such slips.

The present writer has arrived at the conclusion that the author is less assailable as regards his treatment of the practical aspects of his subject than when dealing with more speculative questions. Thus, after giving in a tentative way the results of an analysis of the cementing material in non-plastic bricks, and suggesting a formula to correspond, he proceeds to apply this formula in a chemical equation to explain the reaction by which such cementing material is formed. The statement which accompanies it may constitute a fairly accurate general account of what takes place; but although more than one "if" is expressed or implied in the explanatory sentence, the equation somehow seems to suggest a more intimate knowledge of this particular reaction than is justified by the actual facts, as the author himself distinctly states more than once that the composition of the binding material is not definitely known. Again, in criticising the results of experimental work of F. F. Wright, performed at the Carnegie Institute, Mr. Searle goes so far as to assert that "if F. F. Wright had worked on a large scale and with better facilities, he would probably have realised that his experiments afford a much stronger confirmation of the composition suggested by the author of the present volume than they do of the existence of a zeolite, as the latter, so far as is known, do not possess cementitious properties." This may seem convincing to the author, but to a trained mind the conclusion is very far from being established, even when taking into account the experimental evidence by which he plausibly claims to prove the general accuracy of his conclusion.

With some reservation as regards certain of the matters to which attention has been directed, the work should prove useful for the objects the author had in mind when preparing it. One excellent feature worthy of mention is the comparison table occasionally introduced, showing in one view a number of more or less different processes, or the properties of a variety of different products, etc. There is also a serviceable index.

J. A. A.

THE PANAMA CANAL.

The Panama Canal: Comprising its History and Construction, and its Relation to the Navy, International Law, and Commerce. By R. E. Bakenhus, Capt. H. S. Knapp, and Dr. E. R. Johnson. Pp. xi+257. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1915.) Price 10*s.* 6*d.* net.

THIS book has a claim to authority. It consists essentially of a series of papers which were originally published in the Proceedings of the United States Naval Institute. Of the three authors the first, Mr. Bakenhus, is a member of the Corps of Civil Engineers of the United States Navy, the second, Capt. H. S. Knapp, U.S.N.,

was formerly member of the Naval War College Staff, and the third, Dr. Emery Johnson, is special commissioner on the Traffic and Tolls of the Panama Canal.

Mr. Bakenhus narrates the history of the project, and gives a clear account of the design and construction of the canal. His treatment of the phenomena presented by the landslides is, however, inadequate, and not marked by any originality of thought. They still occur at intervals, seriously reducing the depth of the waterway; it is quite uncertain when they will cease, and until that time comes the canal will not be thoroughly satisfactory as a link in the chain of naval communication between the Atlantic and Pacific Oceans.

Captain Knapp deals with the United States Navy and the Panama Canal, detailing the reductions of sea distance. The strategic aspect of the canal has not received sufficient attention in this country, considering that it was primarily intended for the use of the United States Navy. But if the British public has been in the past somewhat prone to neglect the study of strategy, our condition is one of enlightenment compared to the general misapprehension of such matters by American citizens.

"The United States," says Capt. Knapp, "is not a military nation. There is little consideration and less understanding among the people at large of military matters. The Government has no defined military policy, using military in its wide sense, and it has no defined naval policy."

The plain fact is that the American Government is gambling on the maintenance of the balance of power in Europe. Once let the balance of forces on our side be destroyed and the Monroe doctrine could not be upheld by the naval and military force now at the disposal of the United States, and the whole fabric of American imperial policy would fall. The time which would be required to prepare the United States for war with great Powers is probably under-estimated by most people. The first step must be the education of the people to its necessity, which necessarily takes time. The creation of an adequate staff of trained officers for a large army also takes time; and the building up of a merchant marine, so much required for the navy, is an extremely difficult problem in view of the economic conditions in America.

If the Government of the United States began to-morrow to prepare for a serious war we do not think that the country would be ready in less than twenty years. It is earnestly to be hoped in the interests of Anglo-Saxon civilisation that the great and patriotic democracy of America will turn its keen intelligence to the study of war. V. C.

OUR BOOKSHELF.

Refuse Disposal: a Practical Manual for Municipal Engineers, Members of Local Authorities, etc. By E. R. Matthews. Pp. xiv+160. (London: C. Griffin and Co., Ltd., 1915.) Price 6s. net.

"It is the purpose of this work to set forth modern methods of collection and disposal, embodying the latest practice, so as to enable the municipal engineer and the local councillor to see what is being done in this and other countries"; and information of the type usually accumulated by local authorities in their consideration of the problem of refuse disposal is presented in large quantity having regard to limitations of space.

Given a sound knowledge of the general principles and practice, the engineer will find the collected data with regard to typical plants serviceable, but for the councillor some assistance to the intelligent application of the information presented might well have taken the place of certain non-essential detail and superfluous photographs.

"Discussion" of the advisability of installing destructors for small communities, promised in both preface and text, resolves itself into a description of certain destructors employed in works and institutions, and the statement that destructors "are equally useful for a village of five hundred population as for a city of 500,000."

The bearing upon the cost of disposal, of the special difficulties of collection, of the provision of adequate attention at the destructor, and of finding any practicable use for the heat generated, in a "village of five hundred population" as compared with a city or even an institution, is apparently unrecognised.

The book deals with the uses of destructor clinker and the construction of chimneys, and concludes with some interesting notes upon the principles of vacuum cleaning and dust collecting.

P. G.

A List of Geographical Atlases in the Library of Congress, with Bibliographical Notes. Compiled under the direction of Philip Lee Phillips. Vol. iii. Titles 3266–4087. (Washington: Government Printing Office, 1914.)

The first two volumes of this valuable work were reviewed in NATURE in 1910 (vol. lxxxiv., p. 325), and as the same general plan and arrangement are followed in vol. iii., a brief notice of this will suffice. It deals almost entirely with acquisitions by the Library of Congress since 1909, but such are the resources at the disposal of this fortunate institution that the present list reaches more than half the bulk of the earlier one. In part this may be due to the somewhat fuller notes and analyses—a feature of great value—but the additions to the collection are extraordinarily numerous and important. They include, *e.g.*, copies of Lafreri's rare Italian atlas, and of Waghenaer's "Speculum Nauticum," the absence of both of which was commented on in our previous notice. But few copies of Lafreri, with title, are known, and no two are quite alike; so that the careful collation now given, and the comparison with Norden-

skiöld's list, will be a boon to students, especially in conjunction with the comparative table of maps in other known copies—one in the collection of the Royal Geographical Society—lately supplied by Dr. Wieder, of Amsterdam. Other additions are the rare first edition of Ortelius, and six further editions of Mercator. The most complete of the latter (1639), of which a copy was lately acquired by the Royal Geographical Society, is not, however, to be found, any more than in our own national collection. We still miss a much-needed guide to the arrangement in the form of page-headings.

Lord Kitchener and his Work in Palestine. By Dr. Samuel Daiches. Pp. 88. (London: Luzac and Co., 1915.) Price 2s. 6d. net.

THIS lecture will serve admirably to acquaint the general reader with a little-known aspect of Lord Kitchener's great capacity. His Palestine exploration work falls in the years 1874 to 1878, and the success which attended it revealed him as a successful surveyor, a scientific observer, and a writer of convincing and trustworthy reports. The book provides an interesting and instructive account of his contributions to our knowledge of the geography, geology, and natural history of Palestine.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Manganese-Ore Requirements of Germany.

PROF. CARPENTER, in his article on "Munition Metals" in NATURE of July 15, gives estimates of the resources of the enemy countries in the metals required for war purposes. This information will doubtless prove of great value, especially to those whose duty it is to study the weak points in the armour of our enemies and to devise methods of accentuating those weaknesses; it is consequently desirable that the information so gathered together should be as accurate as possible. In summing up, Prof. Carpenter states that the enemy countries can certainly produce five out of the ten metals considered, without having recourse to imports, these five being iron, manganese, chromium, zinc, lead; whilst he regards it as doubtful whether they can produce from domestic sources sufficient of the remaining five metals—nickel, copper, aluminium, tin, and antimony.

In the course of a lecture delivered in Calcutta recently I had occasion to review the situation as regards manganese-ore, and arrived at the conclusion that the internal resources of the enemy countries in manganese-ore were inadequate to supply more than a small proportion of the internal requirements; so that in my opinion manganese should be transferred to the second group of metals noticed by Prof. Carpenter. Consequently it seems that a short review of the facts of the case will not be out of place

In the following table are collected statistics stated in metric tons of the steel production of the world, of Germany, and of Austria-Hungary, the manganese-ore production of the world, and the manganese-ore secured by Germany, and by Austria-Hungary, for each of the eight years 1906 to 1913:—

(*In Metric Tons.*)

Year	The World		Germany		Austria-Hungary	
	Steel production, in millions of tons	Manganese ore production, in thousands of tons	Steel production, in millions of tons	Manganese ore secured, in thousands of tons	Steel production, in millions of tons	Manganese ore secured, in thousands of tons
1906	49·64	1,932·8	11·14	328·6	1·20	57·4
1907	51·27	2,334·9	12·06	389·7	1·20	96·8
1908	44·36	1,353·6	10·48	331·8	2·03	63·1
1909	53·50	1,576·5	12·05	379·9	1·97	79·9
1910	58·66	1,835·4	13·70	483·3	2·19	92·7
1911	58·27	1,516·7	15·02	411·1	2·36	112·5
1912	72·7	1,640·8	17·87	515·3	2·79	89·7
1913	75·8	2,426·0	19·29	671·0	2·68	96·7
Totals	464·2	14,625·7	111·61	3,510·7	16·42	688·8
	3·15 tons of manganese ore per 100 tons of steel.		3·15 tons of manganese ore per 100 tons of steel.		4·20 tons of manganese ore per 100 tons of steel.	

Note.—These figures are based on statistics given in the "Mineral Industry." [See also "Records, Geolog. Survey, India," xlvi. pp. 144 145, (1915)]. The German "Manganese-ore secured" is the excess of imports over exports, the German "Manganese-ore" being excluded as referring mainly to manganiferous iron ore, which is excluded from this table. The Austrian "Manganese-ore secured" is the excess of production *plus* imports over exports.

From this we see that the German steel industry has shown a remarkable expansion, and that consequently in order to estimate the German requirements we should use only the most recent statistics. In the three years 1911 to 1913 Germany produced an annual average of 17·4 million tons of steel, and secured possession of an annual average of 622,400 tons of manganese-ore, of which 532,500 tons were imported chiefly from Russia and India, and the balance of about 90,000 tons (consisting, by the way, not of high-grade manganese-ore, like the imported material, but of manganiferous iron-ore) was won in Germany.

Turning to Austria-Hungary, we find that during the same three years she produced an annual average of 2·61 million tons of steel, and secured possession of 100,200 tons of manganese-ore, of which 69,400 tons were imported and 30,600 mined within the empire (including Bosnia-Herzegovina).

Assuming, therefore, that the two Teutonic empires require approximately as much manganese-ore when at war as in times of peace, it is evident that they have to provide 532,500 + 69,400 = 601,900 tons of ore to replace their imports in time of peace. There are four possible sources to be considered:—

(1) A development of internal resources.

(2) Imports from their ally Turkey, which posseses manganese-ore deposits.

(3) Imports from neutral countries.

(4) Accumulated stocks.

(1) A consideration of the German deposits of manganese-ore as at present described shows that they are all of small importance. The manganese-ore usually occurs either in irregular lenticular or nodular deposits, or in thin veins, in no case in sufficient quantity to permit of work on a really large scale, whilst a large proportion of the so-called manganese-ore is of very low grade, and more aptly termed manganiferous iron-ore. It does not seem probable that Germany could increase her annual average production of 90,000 tons by more than a few tens of thousands of tons.

The deposits in Austria-Hungary (especially in Bosnia) contain some high-grade managanese-ore, but the published accounts of these deposits do not indicate that an annual production of a little more than 30,000 tons could be increased to several times that amount.

Perhaps by intense activity the Teutonic empires

might increase their output of manganese-ores and manganiferous iron-ores by 100,000 tons annually, but this seems exceedingly unlikely, both from the character of the deposits and from the fact that in times of peace the existence of a large market for manganese-ore must have created every incentive towards intensive working of the domestic manganese-ore deposits.

(2) Turkey is known to have manganese-ores at several localities, but information is very scanty. Of recent years no production has been reported, but a few years ago Turkey produced from 14,000 to 49,000 tons of ore annually. Of the producing localities the only one mentioned in Turkey-in-Europe was the Cassandra district, which is now part of Greece. In Asia Minor manganese-ores have been worked in the provinces of Trebizond and Aidin. In view of Russian naval activity in the Black Sea and the absence of railways, the Trebizond ores must be cut off from Constantinople. Aidin is, however, connected to Constantinople by rail *viâ* Smyrna, and ore from this region could consequently be forwarded, as long as through traffic is permitted at Smyrna by the Allies. But as the Aidin ores are reported to occur in pockets in limestone, no considerable development in this area seems possible. Ores have also been reported as occurring at one or two localities in the country to the south of the Sea of Marmora, and might supply a certain quantity of ore for shipment to Constantinople. Considering, however, the undeveloped state of Asia Minor and the bad communications, it seems improbable that Turkey will be able to aid her allies to any marked extent.

(3) The third possible source of manganese-ore is imports from neutral countries. Now by far the larger proportions of the world's output of manganese-ore comes from three countries, namely, India, Russia, and Brazil, which during the five years 1908 to 1912 (I have not yet been able to obtain complete figures for 1913) contributed respectively 43·8 per cent., 37·2 per cent., and 12·5 per cent., totalling 93·5 per cent. of the world's total production.[1]

The export of Indian ore is prohibited to all destinations except the United Kingdom and France; the export of the Russian manganese-ore to enemy countries is doubtless prohibited, whilst the hard facts of the geographical situation prevent its export to all neutral countries except Rumania and Bugaria,[2] and we can trust our Allies to see that no managanese-ore finds its way to Germany and Austria through this route. There are two reasons why Germany and Austria cannot fall back on Brazil for their supplies of manganese-ore, namely, the British Navy and the fact that Brazilian ore must be more than ever in demand in the United States of America, always its chief customer, now that America is cut off from the Indian and Russian supplies, for the United States, as pointed out in the footnote, has no domestic manganese-ore supplies of her own worth mention.

[1] Prof. Carpenter overlooks the Brazilian production, amounting roughly to 200,000 tons annually, and names the United States of America as one of the three chief producers of manganese-ore in 1913, whereas the 1913 production of the United States of America was the insignificant amount of 4048 tons out of the world's total production of over two million tons. This error is doubtless due to a misleading habit on the part of certain American compilers of statistics of including manganiferous iron-ores under the term manganese-ore. This manganiferous iron-ore production ranges from five to nine hundred thousand tons annually, but the percentage of manganese present in this iron-ore is only from 2 to 20, and such ore cannot be regarded as a manganese-ore, is doubtless never sold as such, and must be excluded from the world's totals of manganese.ore production. Another slight error has also crept into Prof. Carpenter's article: he states, referring to the production of Russia, India, and the United States of America, that "the raw material is pyrolusite, a 'straight' manganese-ore corresponding when pure to MnO_2." This is true only of the Russian ore; the American ore referred to is a manganiferous hematite, whilst the Indian ore is of mixed mineralogical composition. Although some of the Indian manganese-ore is pyrolusitic, by far the larger proportion is a mixture of braunite and psilomelane, whilst in some localities hollandite is an important ore.

[2] [Since this letter was written, Bulgaria has ceased to be a neutral country.—ED.]

The 6·5 per cent. of manganese-ore not produced by the three countries mentioned is obtained from Austria-Hungary, Spain, Japan, Greece, France, the United Kingdom, Sweden, and Italy. Of the three neutral countries amongst those enumerated, Sweden is the only one conveniently situated for Germany. The Swedish annual production is a little more than 5000 tons, and, judging from observations made during a visit to the Swedish manganese mines, I should say that the Swedish production was capable of but very small expansion. Manganese-ore deposits are also known to occur in Bulgaria, but they are of low grade and small extent, so that they could not prove of much value. It seems evident then that Germany and Austria cannot find salvation in neutral countries.

(4) As the three possible sources already considered do not appear to hold out hope that Germany and Austria could obtain their peace requirements of manganese-ore in time of war, it is possible that the enemy countries made provision for this disability by accumulating large stocks of manganese-ore in times of peace. Whether this has been done or not can be deduced only indirectly. From the table on p. 170 we see that during the years 1906 to 1913, taking the world as a whole, 3·15 tons of manganese-ore were produced for every 100 tons of steel made, whilst curiously enough the figures for Germany alone for the same period show that that country received exactly the same proportion of manganese-ore per 100 tons of steel, namely, 3·15 tons.

Assuming that German metallurgy requires for its various purposes as high a percentage of manganese as the rest of the world, it seems reasonable to deduce from the foregoing figures that Germany actually consumed most of the manganese-ore received during the eight years in question, and that therefore by the end of 1913 she could not have accumulated any considerable stocks of manganese-ore. I must note that in making the above calculations I have excluded figures for manganiferous iron-ores from both the German and world's figures[3] as confusing the issue. During the eight years in question, however, the German total production of so-called manganese-ore (mostly manganiferous iron-ore) was 622,500 tons. But there is no reason for regarding this figure as a measure of accumulated stocks. It is instead rather a measure of the fact that Germany really requires a higher amount of manganese-ore per 100 tons of steel produced than most countries, owing to the necessity of adding manganese-ore or manganiferous iron-ore to the blast-furnace burden in smelting the sulphurous phosphoric minette iron-ores of Lorraine. During the same eight years, 1906–13, Austria-Hungary obtained 4·20 tons of manganese-ore for 100 tons of steel made. I have no information available to show whether or not there are any peculiarities in Austrian metallurgy requiring the use of a larger amount of manganese-ore than usual. If there are not, then these figures suggest an accumulation of stocks to the extent of about 175,000 tons by Austria by the end of 1913. The conclusions arrived at are admittedly open to considerable doubts, but it seems probable that by the end of 1913 the Teutonic Powers had not accumulated more than 200,000 tons of manganese-ore, and possibly considerably less.

At present I have been unable to obtain statistics relative to German imports of manganese-ore in 1914, except that there was nothing abnormal in the amount sent from India up to the outbreak of war. Had

[3] Manganiferous iron-ores are produced by the following countries:—

	Average for 1908–12
United States of America	686,302 metric tons
Germany	81,040 ,,
Greece	41,842 ,,
Italy	15,165 ,,

Germany purchased abnormally from Russia during the first seven months of 1914 the fact would probably have been reflected in an increase in the price of manganese-ore during the year. As a matter of fact, the price per unit of manganese-ore fell steadily from a maximum of 12 to 12½ pence in January, 1913, to 9¼ to 9½ pence in July, 1914.

From what precedes it seems justifiable to conclude (*a*) that on the outbreak of war the Teutonic Powers had no great accumulated stocks of manganese-ore, perhaps a maximum of 200,000 tons; (*b*) that, assuming war conditions necessitate a maintenance of the iron and steel industries of those two countries at a peace standard, about 600,000 tons of ore a year must be obtained from fresh sources to replace imports in time of peace; (*c*) allowing that the Teutonic Powers might succeed in increasing their internal production by 100,000 tons and obtain 50,000 tons of manganese-ore from Turkey, if the Allied fleets could prevent all manganese-ore from outside from reaching Germany and Austria these countries would be faced with a shortage of 250,000 tons of manganese-ore in the first year of war, and with a shortage of 450,000 tons per year afterwards, increased to 500,000 tons per annum once the Dardanelles are forced.

The Germans will doubtless find means of dispensing with the use of manganese-ore as much as possible, and they may devise methods of utilising the manganese silicate, rhodonite, of which they appear to possess a considerable quantity; but it seems inevitable that the shortage of manganese-ore, once it is felt, will hamper seriously the German iron and steel industries.

It appears therefore to be of the utmost importance that every effort should be made by the Allied fleets to prevent smuggling of manganese-ore (or ferro-manganese and spiegeleisen) into Germany and Austria, either direct or through neutral ports. It is to be noted that of the small countries adjoining the enemy countries the only one manufacturing iron and steel is Sweden, which does not show either manganese-ore, ferro-manganese, or spiegeleisen, amongst her imports in normal years.

L. LEIGH FERMOR.

Calcutta, September 2.

Jupiter's Two Principal Markings.

AT intervals during the work of a comparison of stellar magnitudes, the 26-in. reflector has been turned on Jupiter, in order to determine the present rotation period of the various surface currents, and it is hoped that results of some value will be obtained by the end of the present apparition. The following longitudes, based on transit estimates, of the two most important objects on Jupiter, viz., the S. Tropical Disturbance and the Red Spot Hollow, have been determined:—

S. Tropical Disturbance

Date 1915	P. end	f. end
Sept. 11	28·3°	—
13	25·9°	—
20	23·5°	—
21	—	117·7°
26	—	112·8°
28	—	111·6°
30	20·4°	110·4°
Oct. 1	—	109·7°

Red Spot Hollow

Date 1915	P. shoulder	f. shoulder
Sept. 10	—	260·2°
12	224·6°	—
17	224·3°	261·2°
19	224·1°	262·8°
27	—	260·2°
29	—	260·2°

The S. Tropical Disturbance is more than 90° in length at the S. equatorial belt, and in point of size forms a wonderful object when centrally on the meridian. Its length is such as to extend nearly from limb to limb. It first appeared as a comparatively small object in the spring of 1901, and although in the meantime it has fluctuated in size considerably, it exhibits no signs of decadence.

When the air is steady, the Red Spot can be seen without difficulty in the 26-in. reflector. It is, however, well to state that it is now no more distinct than it has been for many years. Displaced towards the f. side of the Hollow, its following end coincides almost with the longitude of the f. shoulder of the Hollow, while its northern contour is nearly in line with the S. edge of the S. equatorial belt. It will be seen from the above longitudes that the length of the Hollow is roughly 38°, a similar dimension having obtained during the last fifteen years.

October 2. SCRIVEN BOLTON.

The Orionid Meteoric Shower.

THE ensuing return of these meteors will deserve, and probably will repay, observation. The moon will be full on October 23, and will somewhat interfere with the display, but it is rather a long-continued one, and may be favourably witnessed in the mornings from about October 17–21 before sunrise.

From a great many observations made at Bristol, and which I have recently discussed, I believe that the shower extends from the first week in October to the first week in November. I have determined two radiants, as follows, from my collected materials from 1873 to the present time:—

October 3–12—91¼° + 14½°; 10 meteors.
October 25–November 7—92½° + 14°; 18 meteors.

For the intervening period between October 12 and 25 I have a number of radiants of this well-known and annually recurring shower. The two radiants given above are adequately supported by a sufficiency of streaking meteors, and I believe represent genuine positions, but it cannot absolutely be proved that they are based on the flight of true Orionids. Remembering, however, that the radiation is from a fixed point at about 92° + 15° for certainly a fortnight near the maximum, I believe I am justified in ascribing a month's activity to the shower. It would be serving a useful purpose if observers watched the display very carefully this year, and ascertained the place of the radiant point accurately between, say, October 15 and 25. The fact of this stationary radiant would then be no longer open to criticism.

Visibility of Distant Objects in Warfare.

I WAS much interested in the article on "Visibility of Distant Objects in Warfare" in NATURE of September 30. The question is of vital importance to many who, like myself, spend much of our time in artillery observing stations.

I believe a good deal of misconception exists as to the reasons why the Germans use various-coloured sandbags. It may be that their use is intended to make for invisibility, but I am inclined to think that it is primarily due to their lack of materials for making sandbags. They lack jute, and are consequently forced to make use of the stocks of various-coloured dress materials, in some cases indeed using the uniforms they have taken from the bodies of any men who may have been killed near their trenches. It is interesting to note that the colour most commonly employed in making their latest sandbags is a pinky-red.

In dealing with the question of visibility, it seems to me that the whole tendency in designing uniforms and in making fortifications is to ignore the important consideration of shadow, which Thayer has shown to have such an important bearing on the coloration of animals.

I have hopes that your article may induce some man of science to take the matter up, and perhaps submit his conclusions confidentially to Lord Fisher's Commission.

ARTILLERY OBSERVING OFFICER.

October 6.

Distances at which Sounds of Heavy Gun-firing are Heard.

IN NATURE of September 30 I see a letter from Dr. Henry de Varigny on the above subject. It reminds me of September 2 last year, when I noted in my diary:—"The day here (400 ft. elevation on scarp of the Lower Greensand overlooking the Weald) was brilliantly fine and warm, without a cloud, South Downs misty, a gentle wind from the south-eastward. My sister heard very distant continuous rumbling, like guns, all the morning up to 1.30, and several times mentioned it when sitting in the garden; my coachman and a maid-servant also heard it. What was going on that day in France it would be interesting to know; there was no gun-firing on the coast of Sussex." I wrote, after taking bearing on map:—"It may possibly be as far as 150 miles to Amiens." I find twice since, and only a fortnight ago, similar continuous rumbling has been heard, but unfortunately the date not noted. I am much too deaf to hear such sounds myself. H. H. GODWIN-AUSTEN.

Nore, Godalming, October 1.

THE only papers on this subject with which I am acquainted are the following:—(1) The distance to which the firing of heavy guns is heard, NATURE, vol. lxii., 1900, pp. 377–79; (2) the audibility of the minute-guns fired at Spithead on February 1, *Knowledge*, vol. xxiv., 1901, pp. 124–25. Reference might also be made to NATURE, vol. xli., 1890, p. 369, and vol. lx., 1899, p. 139. The firing during the funeral procession of the late Queen Victoria was heard to a distance of 139 miles from Spithead. There is therefore no reason why firing along the Belgian coast should not, with favouring winds, be heard for many miles inland from our coasts. The air-vibrations affect pheasants and other birds (probably by swaying the branches of trees) for some distance after they cease to be perceptible to the human ear, as was widely observed on the occasion of the North Sea battle on January 24. I would suggest that observations of this kind should also be forwarded to Dr. de Varigny.

I may add that the literature relating to explosions is more extensive and much more valuable than the above. Prof. Omori's memoirs on the eruptions of the Asama-yama (Bull. Imp. Earthquake Inves. Com., Tokyo, vol. vi., 1912, pp. 1–147, and vol. vii., 1914, pp. 1–215) contain many interesting observations. A few cases of recent explosions in factories are noticed in NATURE, vol. lxi., 1899, pp. 91–92, and *Knowledge*, vol. i., 1904, pp. 94–95. Mr. S. Fujiwhara has lately published a valuable memoir on the abnormal propagation of sound in the atmosphere (Bull. of the Centr. Meteor. Obs. of Japan, vol. ii., pp. 1–143). This contains a mathematical discussion of the problem, with special reference to the observations recorded by Prof. Omori. References to recent German literature on the subject are also to be found in this memoir.

CHARLES DAVISON.

The late Prof. E. A. Minchin on "The Evolution of the Cell."

PROF. E. A. MINCHIN was looking forward with interest at the time of his death to distributing the "extra prints" of his Manchester address, which was three times as long as will appear in NATURE. These "extras" are now in my possession, but I have no means of getting Prof. Minchin's "list." I shall be very happy to send a copy to anyone who will send me a postcard asking for it.

EDWARD HERON-ALLEN.

Large Acres, Selsey Bill, Sussex, October 12.

DEATH FROM STATIC CHANGES IN ATMOSPHERIC PRESSURE.

AS mentioned in a note in NATURE of July 8 (p. 515), M. R. Arnoux has found that a momentary diminution of at least 350 mm. of mercury in barometric pressure may be produced within three metres of a bursting high-explosive shell; and he suggests that the sudden diminution of pressure may cause death by the liberation of gas-bubbles in the blood, and consequent blocking of the circulation.

In his book on "La Pression Barométrique," published nearly forty years ago, Paul Bert proved that the various symptoms which often follow decompression from high atmospheric pressure are due to liberation of gas-bubbles in the blood or tissues. In diving work, and various kinds of engineering work under water or in water-bearing strata, men are exposed to high atmospheric pressure. During the exposure the blood passing through the lungs takes up in simple solution an extra amount of gas in proportion to the increased partial pressure of each gas present in the lung air. The gases present are oxygen, carbon dioxide, and nitrogen. The extra free oxygen taken up is, however, very small in amount as compared with the total free and combined oxygen taken up at normal atmospheric pressure; and since much of this total is used up as the blood passes through the tissues, there is no appreciable rise in the very low partial pressure of oxygen in the blood of the systemic capillaries or veins or in the tissues. There is also no rise in the low partial pressure of carbon dioxide in the lung air or blood, since the breathing is so regulated as to maintain a practically constant partial pressure of carbon dioxide in the lung air. On the other hand, the partial pressure of nitrogen in the blood leaving the lungs rises in proportion to the increased atmospheric pressure, and as no free nitrogen is used up, every part of the body becomes gradually saturated with nitrogen at this increased partial pressure. If, now, the atmospheric pressure is again reduced to normal, the blood and semi-liquid tissues of the body are left in a condition of super-saturation with nitrogen, and as a consequence bubbles, consisting almost entirely of nitrogen, are apt to form, and to cause very serious effects. Death may result from blockage of the circulation through the lungs or heart-muscle; paralytic attacks may be caused by blockage in the brain or spinal cord; while characteristic localised pain (so-called "bends") may be produced by the presence of bubbles elsewhere.

It is clear that if the atmospheric pressure is considerably diminished from normal, a similar condition of super-saturation of the body with nitrogen will exist, so that bubbles may be formed; and it is natural to suspect that a sudden, though only momentary, diminution, due to the bursting of a shell, might liberate bubbles. There are, however, facts which tell strongly against this hypothesis.

In the first place, it must be pointed out that

a considerable interval of time elapses between decompression and the onset of symptoms due to bubble-formation. It is commonly fifteen or twenty minutes, and often far more, before the appearance of symptoms caused by bubbles after rapid decompression from a high atmospheric pressure. Sudden effects, such as those said to be produced by bursting shells, are never observed, however rapid the decompression may have been. The formation of bubbles of sufficient size to do any harm is evidently a process which takes considerable time. A momentary decompression, even if it were extreme, could scarcely, therefore, have any serious effect.

If, however, minute bubbles were formed, they would rapidly disappear again when the momentary wave of negative pressure had passed. Abundant experience has shown that there is no more rapid and certain means of treating the symptoms due to bubbles than recompression. When men who have come out of compressed air are affected, they can be relieved by returning them to the compressed air from which they came, or placing them in a medical recompression chamber provided for the purpose. As an instance of the application of this treatment, a recent case may be recorded of a naval diver who, owing to some emergency, had returned to surface suddenly, without carrying out the prescribed regulations for safety. About twenty minutes afterwards he became ill, lost consciousness, and was apparently dying from bubble formation. In accordance with the recommendations for dealing with such a case, in the absence of a re-compression chamber, his helmet was screwed on, and he was then lowered to the depth from which he had come. He recovered consciousness rapidly, and was soon able to answer the telephone, after which he was safely brought up, with due precautions. In the case of a man exposed only momentarily to decompression, the remedy for bubble-formation is, of course, automatically applied at once, since he returns at once to the pressure from which he was decompressed.

Recent investigations in this country have shown that symptoms due to bubble-formation do not occur unless the absolute barometic pressure is diminished by more than half. Thus it is safe to decompress rapidly from two atmospheres' pressure to one, or from six to three; and the Admiralty regulations for safety from bubble-formation in diving are based on this fact. Hence a sudden diminution of pressure from normal to half an atmosphere would not be dangerous, even if the decompression were a prolonged one. The momentary diminution observed by M. Arnoux was, however, only 350 mm., or not quite half an atmosphere.

It appears, therefore, to be impossible to accept the bubble theory of the action of bursting shells in killing men without visible wounds or mechanical injury. The newspaper accounts of men being killed by bursting shells in some sudden and mysterious manner, without wounds or bruises, appear to be imaginary. The experience of those who have been exposed to shell fire does not, so far as the writer's inquiries go, lend any support to these accounts. Neither poisonous gases nor any other known cause would account for men being instantly killed without mechanical injuries. An air-wave of sufficient violence may doubtless knock men over and inflict mechanical injury capable of causing death; but the actual fatal injuries caused by shells appear to be almost all due to fragments of metal or of stone or other material set in motion by the explosion.

J. S. HALDANE.

DR. J. MEDLEY WOOD.

WE record with regret the death, on August 26, at the Botanic Gardens, Durban, in his eighty-seventh year, of the veteran director of the Natal Herbarium, Dr. John Medley Wood. Dr. Medley Wood was a native of Mansfield, Nottinghamshire, and had resided in Natal for sixty-three years.

Before his appointment as curator of the Natal Botanic Gardens in 1882 he practised for a time as a solicitor, and then went trading to Zululand, afterwards devoting himself to farming. His home was then at Inanda, where he spent some ten years, and besides undertaking experiments in the cultivation of arrowroot and castor oil he interested himself in the local flora, and contributed large and important collections of Natal plants to Sir Joseph Hooker for the National Herbarium at Kew. His activities in this latter direction were naturally stimulated on his appointment to the Gardens. Not only did he continue to enrich the collections at Kew, but he founded and gradually built up the very valuable Herbarium of Natal plants at Durban, which is a model of what a colonial herbarium should be.

When Dr. Medley Wood was appointed curator of the Natal Garden in February, 1882, by the Durban Botanic Society, the condition of the garden was by no means flourishing, but as funds allowed he was not long in restoring it to a condition of beauty and usefulness. The value of his work was so far appreciated that the Government grant towards the upkeep of the garden and the maintenance of the collections was gradually increased, and in 1902 the new building for the Herbarium was completed. In 1909 the Herbarium collection consisted of some 43,000 mounted and classified specimens. Medley Wood's publications on the Natal flora form valuable contributions to botanical science. In 1886 he published an analytical key to the orders and genera of Natal plants, but the most important of his works is that entitled "Natal Plants," of which six volumes have been published, the first part, consisting of fifty plates with descriptions, having appeared in 1898. Other useful publications include his "Handbook to the Flora of Natal" (1907) and a "Revised List of the Flora of Natal" (1908). His "Guide to the Trees and Shrubs in the Natal Garden," published in 1897, giving dates of planting, is a valuable record of

the work he did for the colony in the introduction of useful and interesting plants. He also did much for the improvement of the sugar-planting industry, and investigated many other problems of economic importance. In 1908 the Government grant for the garden and herbarium was much reduced, but although sadly hampered Medley Wood did not relinquish his efforts, and he was keenly interested in his work up to the end.

Dr. Medley Wood was appointed director of the Natal Garden, but he ceased to hold that office when it was recently handed over to the Corporation of Durban, and he then became director of the Natal Herbarium.

Two years ago the honorary degree of D.Sc. was conferred upon him by the University of the Cape of Good Hope, an honour which was a very fitting recognition of the great value of his services to botanical and agricultural science in South Africa, and gave much pleasure to his many friends.

NOTES.

We notice with much regret the announcement of the death, at ninety-two years of age, of M. J. H. Fabre, whose patient studies of the life-histories of insects, as recorded in his "Souvenirs Entomologiques" and other works, placed him in the front rank of outdoor naturalists throughout the world.

The Faraday Society will hold a general discussion on "The Transformations of Pure Iron" on Tuesday, October 19. The president, Sir Robert Hadfield, will preside over the discussion, which will be opened by Dr. A. E. Oxley, of Sheffield. Tickets may be obtained from the secretary of the Faraday Society, 82 Victoria Street, S.W.

We learn from *Science* that Dr. Max Planck, professor of physics at Berlin, and Prof. Hugo von Seeliger, director of the Munich Observatory, have been made knights of the Prussian Order of Merit. Dr. Ramón y Cajal, professor of histology at Madrid, and Dr. C. J. Kapteyn, professor of astronomy at Groningen, have been appointed foreign knights of the same Order.

The council of the Chemical Society has arranged for three lectures to be delivered at the ordinary scientific meetings during the coming session. The first of these lectures will be delivered on November 18, by Dr. E. J. Russell, who has chosen as his subject, "The Principles of Crop Production." The titles of the two later lectures to be delivered on February 3 and May 18, by Prof. W. H. Bragg and Prof. F. Gowland Hopkins, respectively, will be announced later.

The new session of the Royal Geographical Society will open on November 15 with a paper by the president, Mr. Douglas W. Freshfield, on the southern frontiers of Austria. Among other papers to be read at evening meetings are:—The work of the Peru-Bolivia Boundary Commission, Sir Thomas H. Holdich; The geographical and ethnic position of the Slavs between the Adriatic and the Drave, Sir Arthur Evans; Cyrenaica, Prof. J. W. Gregory; The Troad and the command of the Dardanelles, Dr. Walter Leaf; The valley of Mexico, A. P. Maudslay; and the Gold Coast, A. E. Kitson.

A Reuter message from Paris states that the French Minister of War has appointed a consulting committee of experts attached to the Under-Secretaryship of Military Aeronautics. Among other well-known names, the Committee, which is presided over by the Under-Secretary himself, includes M. Appell, who occupies one of the chairs of mechanics at the Sorbonne; M. Robert Esnault; M. Pelterie; M. Deslandres, director of the Meudon Obsrvatory; M. Deutsch, president of the Aero Club; M. Renault; M. Clement Bayard; M. Eiffel; and M. Kling, director of the Municipal Observatory.

We regret to notice that the *Engineer* for October 8 announces the death in action in France of Capt. W. McLeod Macmillan, of the 11th Argyll and Sutherland Highlanders. Capt. Macmillan was the chairman and managing director of the old-established shipbuilding firm of Archibald Macmillan and Son, Dumbarton, and was in his fortieth year. He was educated at Fettes College, Edinburgh, and succeeded his father in 1910. He acted for a period as chairman to the Clyde Shipbuilders' Association, and was a member of the council of the Institution of Engineers and Shipbuilders in Scotland.

At the recent International Congress of Mathematicians at Cambridge it was decided that the next congress should meet at Stockholm in 1916. The King of Sweden offered a gold medal with the likeness of Karl Weierstrass and a sum of 3000 crowns for an original important discovery in the domain of the theory of analytical functions. Competing manuscripts were to have been sent to the editor of *Acta Mathematica* before October 31 next, the centenary of the birth of Weierstrass. We are informed by Prof. Mittag-Leffler that in accordance with a widely expressed wish, the King of Sweden has decided, in view of the European war, to postpone the last day for the receipt of competing memoirs until October 31, 1916.

It is announced in the *Pioneer Mail* that the third annual meeting of the Indian Science Congress will be held in Allahabad from January 13–15, 1916, when Sir Sidney Burrard, F.R.S., will be president. The chief sections will be physics, chemistry, zoology, botany, agriculture, and ethnology, and the presidents of the respective sections Dr. Simpson, of the Meteorological Department; Dr. Sudborough, of the Research Institute, Bangalore; Dr. Woodland, of Allahabad; Dr. Howard, of Pusa; Mr. Coventry, of Pusa; and Mr. Burn. It is hoped that the local committee will persuade Dr. Bose to give a public lecture on his own researches. The local secretaries for this year are Dr. Hill, of Muir College, and Mr. P. S. Macmahon, of the Canning College, Lucknow, to the latter of whom all communications should be addressed. The congress is under the general control of the Asiatic Society of Bengal.

We announce with regret the death in action in Flanders on September 25 of Major A. J. N. Tre-

mearne, of the 8th Seaforth Highlanders. An Australian by birth, he served in the South African war, and later obtained an appointment in the Nigerian Police Force. There he acquired proficiency in the Hausa language, and studied the anthropology and folklore of this people. He then gained a scholarship at Christ's College, Cambridge, and was awarded the diploma in anthropology. The results of his work in Nigeria were published in "Hausa Superstitions and Customs," and "The Tailed Hunters of Nigeria." Later on he visited North Africa and published a work on demonology, entitled "The Ban of the Bori," in 1914. His sympathetic knowledge of the African races enabled him to carry out valuable field work, and the results of this were published in numerous papers in the Transactions of the British Association, the Royal Anthropological Institute, and the Folklore Society. It will be difficult to fill his place as a competent field anthropologist.

THE *Revue Scientifique* for September 18 reproduces an important address delivered at the Conservatoire des Arts et Métiers in February, by Prof. J. Violle. Its subject is the future of the physical industries of France after the war. By a comparison of the statistics of import and export of the countries of Europe he shows how France has in the last twenty or thirty years lost its place as a leading constructor of mechanical, electrical, and optical apparatus for the civilised world. He urges on the Government the importance of providing schools for the training of skilled workmen, of a National Laboratory of Weights and Measures on the lines of the National Physical Laboratory of this country, the Bureau of Standards of Washington, and the Physikalische Reichsanstalt of Germany. The country urgently needs such a central institution to which the scientific problems which arise in industry may be taken for solution. Behind these requirements he recognises the importance of following the example of Russia and removing the formidable temptation of alcohol from the workman's path, and points out finally how in the workshop, in the field, no less than in the army, France is suffering from "the shameful reduction in the birth rate."

THE abnormal condition of the market for feeding stuffs caused by the war suggested to Prof. Hendrick and Mr. W. J. Profeit the experiment described in Bulletin No. 20 issued by the North of Scotland College of Agriculture. The object of the experiment was to determine the feeding value of palm-kernel cake in comparison with linseed and decorticated cotton cakes. The first of these cakes is a feeding stuff hitherto little used in this country, almost the whole production going to the Continent, chiefly to Germany, where it has always found a ready market. Now, however, large stocks of palm-kernel cake are, or shortly will be, at the disposal of the home feeder. In Prof. Hendrick's experiment thirty head of cattle were divided into three lots, each consisting of six heifers and four bullocks. Throughout the period of eighty-four days covering the experiment, each lot of animals was fed with one variety of cake mixed with locust-bean meal in addition to a diet of swedes and straw to all alike. The three lots of cattle all did well, and the return in live weight increase was practically the same for each kind of cake. The monetary return from the palm-kernel cake was, however, considerably better than that given by either cotton or linseed cakes at present prices. Some doubts have been expressed as to the keeping properties of palm-kernel cake owing to the oil becoming rancid, but no difficulty of this kind was found after nine months' storage. The high percentage of fibre in this cake does not appear to affect the digestibility of the feeding stuff.

THE Board of Agriculture and Fisheries is circulating an appeal by Lord Selborne to the farmers and occupiers of land in England and Wales calling on them to produce as much food as possible during the coming year. No hope of financial support from the State is held out, but farmers are asked to do their part in increasing the supply of food as the special war service which they can render to their country. Leaving the precise means to be adopted to the farmer's judgment and to the advice of his friends and neighbours, it is suggested that the object in view may be attained by one or more of the following methods:—(*a*) By ploughing up the poorest permanent pasture and so increasing the arable land; (*b*) by shortening the period for which existing arable land is kept under clover or rotation grasses; (*c*) by improving the remaining grass land so that it will carry more stock; and (*d*) by reducing the acreage of bare fallow wherever possible. Lord Selborne realises the many special difficulties that have to be overcome, of which the chief is that of labour. Arrangements have already been made that men skilled in agricultural work, such as shepherds and engine-drivers, are not to be accepted for enlistment, yet this difficulty will remain with regard to the supply of ordinary farm labour. Machinery is to be set up to link the actual producer with the Board of Agriculture through the agency of local committees in each district, acting under the guidance of a War Agricultural Committee for each county. The farmer should consult his local committee on any problems or difficulties that may confront him. By this means it will be possible for the President of the Board to be kept informed of the needs of farmers throughout the country and to secure that all the help that can be given them is placed at their disposal.

THE idea of a universal permanent or durable peace has seemed to many minds merely Utopian. But the peculiar circumstances of a world-war are more and more forcibly impressing upon the world the desirability of realising the idea, and are also beginning to make clear the necessary bases of such realisation. The present war may be termed scientific from many aspects, and a permanent world-peace can only be attained by scientific study of the causes of war and of the possible ameliorating conditions. Several publications dealing with these matters have reached us recently. The Swiss thinker, Prof. August Forel, shows, in his "Die Vereinigten Staaten der Erde," how the causes of war and of this war are rooted in every department of social life and organisation. The *brochure* has many interesting *aperçus* on national psychology, and the meaning of race-hatred, war-

fever, and the like. It is worth translating into English for its scientific insight alone. In 1795 Immanuel Kant drew up a programme, "Zum Ewigen Frieden," which is still a classic. Messrs. George Allen have been well advised to issue this with translation in pamphlet form. The manifesto of the Central Organisation for a Durable Peace, at 51 Theresiastraat, the Hague, gives a minimum-programme for the bases of such peace, chiefly to invite suggestions and co-operation. It is the result of the international meeting held at the Hague last April. The *Comité Suisse pour l'étude des bases d'un traité de paix durable* have, on the lines of the Hague manifesto, issued a valuable *mémoire*, not individual, like M. Forel's, but impersonally legal. It contains references to articles of conventions and to recent literature on the general subject of permanent peace. Certainly there is now in process of creation a science of peace-maintenance, the successful results of which may regenerate both national and international life.

IN the issue of the Journal of the Royal Anthropological Institute for January–June, 1915, the president, Prof. A. Keith, publishes his presidential address on the Bronze age invaders of Britain. He fixes the date of this invasion about the year 2000 B.C., and he states that we are not yet in possession of sufficient evidence to determine how far this round-headed race replaced the older inhabitants of Britain. There were several parts of England, Wales, Scotland, and Ireland which they failed to penetrate; at least, we have not found in these parts their peculiar "round-barrow" graves. The problem is to ascertain the birthplace of this race. We find merely secondary settlements along the eastern shores of the North Sea and at the possible points of their embarkation. The hypothesis that they came from Asia may be discarded, as the belief is growing that our own continent may have produced its own races. The centre of dispersion was probably the central mountainous region of Europe. In Denmark we recognise two invading waves of round-heads, but the older or neolithic wave contained men marked by all the characters which we recognise in the English round-barrow people. They also settled in south Sweden, south-west Norway, at the mouths of the Elbe, Weser, and Ems, advanced down the Rhine valley, and reached the coast of Normandy. The paper deserves attention as an able summary of the results of modern research.

THE *Indian Journal of Medical Research* for July (vol. iii., No. 1) contains a number of valuable papers on subjects relating to tropical medicine. Major MacGilchrist discusses the relative therapeutic value in malaria of the cinchona alkaloids, and finds that hydroquinine is clinically superior to quinine and all the others.

THE report of the director-general of public health, New South Wales, for the year 1913, recently issued, contains a mass of statistical and other information relating to the public health of that colony. One of the most interesting sections deals with an outbreak of small-pox in Sydney, showing how mild and insidious this disease may sometimes be. It is also of interest because the disease was successfuly inoculated upon the calf.

THE third report of the Government Bureau of Microbiology, New South Wales, contains a number of valuable reports on the diseases of man, animals, and plants occurring in the colony, and on agricultural and economic problems. A diphtheroid bacillus was isolated from a number of surgical lesions in children. It was, however, not the true diphtheria bacillus; it conformed to one particular and distinctive type, which can be identified with comparative ease, and is named by Dr. Cleland the *Bacillus chirurgicalis*. The organism was usually non-virulent to guinea-pigs.

MANY biochemical reactions proceed in the manner of a mono-molecular reaction, as, for example, the killing of micro-organisms by heat and by disinfectants. T. Madsen and T. Watabiki show that the same holds good for the destruction of "complement" of blood-serum and of "hæmolytic amboceptors" by heat, the relation between the temperature, and the rapidity of reaction in both cases conforming in general to the law of van't Hoff and Arrhenius (*Bull. de l'Acad. Roy. des Sc. et des Lettres de Danemark*, 1915, No. 2).

"THE bird as a labourer," remarks a writer in the autumn number of *Bird Notes and News*, "is not recognised by the Board of Agriculture." This is indeed the case, because the Board has not yet risen to a full sense of its responsibilities. When it does it will establish a Bureau of Ornithology, such as has long been at work, both on the Continent and in the United States. In these countries the value of birds as destroyers of insect pests and of noxious weeds is fully recognised. The present number of our contemporary contains some valuable information on the subject of birds in relation to the farmer and gardener.

DR. J. M. DEWAR, in the *Zoologist* for September, continues his observations on "The Relation of the Oystercatcher to its Natural Environment." The present notes are concerned with the summer environment, and the nature of the nesting-sites and sources of food supply. The breeding-stations within the area examined fall into three distinct habitats—a hill-stream, a river-valley, and a beach habitat. But a strong similarity exists between all the stations of each habitat, variability of the factors being much less pronounced than in the winter environment. In such inland stations earthworms, tipulid, and coleopterous larvæ form the staple food of the young. In the lake-beach area a large sand-bank at the head of the loch, and a boulder area on its north shore, are used every year by the birds that have failed to breed, as places of assembly for bathing, sunning, and other activities. We should have been glad of some statement as to the number of birds breeding at these stations. But these details will perhaps be given in a later article, for the series is not yet completed.

MR. A. H. CLARKE, in the *American Naturalist* for September, discourses at length on asymmetry as developed in the genera and families of recent Crinoids. He maintains that the less favourable the

environment as a whole the greater becomes the proportion of asymmetrical forms. The two main factors in producing asymmetry are bathymetrical and thermal. This feature is least developed at the optimum temperature for crinoid life, and most developed in temperatures which are phylogenetically too warm or too cold. Excessive cold appears to be the determining factor in the asymmetry of the genus Promachocrinus; while the opposite condition, excessive warmth, similarly affects the family Comasteridæ. Internal unfavourable conditions, the author insists, have also to be taken into account, such, for example, as are induced by incipient phylogenetical degeneration through type-senescence, as in the Plicatocrinidæ, which, in recent seas, represent the almost exclusively Palæozoic Inadunata.

A FURTHER instalment of Mr. J. F. Duthie's "Flora of the Upper Gangetic Plain" has now been published. The present section, which forms part i. of vol. iii., deals with the families Nyctaginaceæ to Ceratophyllaceæ, and occupies 168 pages. The Euphorbiaceæ and Urticaceæ are among the most important of the families included, the former with twenty-one genera and the latter with seventeen. The genus Ficus, which has some 600 species, is represented in the Upper Gangetic plain by eighteen species, among which are such well-known trees as *Ficus bengalensis* and *F. religiosa*.

Monthly Weather Reviews are published with great regularity by the Government of India, and the issue for March, 1915, shows considerable activity on the part of the meteorological department. The review, which is drawn up under the superintendence of Dr. G. C. Simpson, is based on observations taken daily at 8 hrs. at 215 stations, and on additional observations taken at 10 hrs. and 16 hrs. at 14 stations. For the summary of rainfall, observations are used from about 2,300 stations. March was remarkably wet over by far the greater part of the Indian area, and with these conditions the air was damper and the sky more cloudy than usual in most parts of the country. The departures from normal temperature were generally feebly marked, whilst the barometric pressure in the plains was in excess of the normal. Observations are given of solar, magnetic, and seismic disturbances. Much detailed information can be obtained from the tabular results and from the illustrations contained in the review.

RAINFALL values for August, 1915, are given in *Symons's Meteorological Magazine* for September, and the results show very varied conditions for the month. Last August is so commonly quoted as being wet that it is somewhat surprising to find that the percentage of the average rainfall was 72 for England and Wales, 68 for Scotland, 83 for Ireland, and 75 for the British Isles as a whole. The London rainfall was 95 per cent. of the average, from the observations at Camden Square, but it may be remarked that the rainfall was much heavier at South Kensington, the recording station of the Meteorologcal Office, where the fall was about 50 per cent. above the normal. The values given for the several stations in different parts of the British Isles show very varying results. The greatest excess on the normal occurred at Shoeburyness, where the fall was 166 per cent. of the average, and this is at a station which is notably one of the driest in the whole kingdom. Scathwaite, which is normally the wettest portion of the kingdom, had only 37 per cent. of the average, which is as great a deficiency for August as any part of the country. The map giving the rainfall for the Thames Valley shows that the rains were extremely irregular and patchy, particularly in the neighbourhood of London.

A NOTE on the divide produced by a plate in a moving liquid is contributed by Mr. Tsuruichi Hayashi to the *Tôhoku Mathematical Journal*, viii., 1. The author arrives at the conclusion that "the divide is the locus of point (*sic*) from which two shortest equal normals can be drawn to the periphery of the plate immersed." But this result is based on an assumption for which justification is sought in quotations from Duchemin's results, taken from De Villamil's recent book on "Motion of Liquids," with explanatory additions in square brackets. From these extracts the Japanese writer bases his conclusions on the assumption that the lines of flow along the face of the plate are straight lines normal to the boundary. Unfortunately, however, this assumption appears to be based on a distorted quotation of Duchemin's actual statements, and the reference to "curved" diagonals in the case of a rectangular plate, which is attributed to Duchemin, would appear to "unjustify" (if such a word may be made) the interpretations which have led to the present writer's conclusions. It is easy to construct cases where the result would evidently not hold good, in particular in the case of figures with re-entrant angles, or again, figures composed of two or more separate areas.

AN important paper, which marks a real advance in the chemistry of the sulphites, has been contributed to the September issue of the Journal of the Chemical Society by Mr. C. S. Garrett from the University of Liverpool. It is shown that no power of selective absorption of light is possessed by the neutral sulphites, such as Na_2SO_3, or by the two types of alkyl sulphites, such as $C_2H_5.O.SO.O.C_2H_5$ and $C_2H_5.SO_2.O.C_2H_5$. Sulphurous acid in aqueous solutions, on the other hand, gives a very well-marked maximum of absorption at wave-length 2760. The important discovery is now announced that the acid sulphites, such as $NaHSO_3$, and the metabisulphites, such as $Na_2S_2O_5$, show no selective absorption in freshly prepared aqueous solutions, but develop this property after keeping for some weeks, especially if exposed to light. It is suggested that this alteration of properties is due to the chemical changes represented by the equations—

$$2NaHSO_3 \rightleftharpoons Na_2SO_3 + H_2SO_3$$
$$H_2O + Na_2S_2O_5 \rightleftharpoons Na_2SO_3 + H_2SO_3,$$

whereby the non-absorbent compounds on the L.H. of the equation are converted into a non-absorbent sulphite and an absorbent form of sulphurous acid. Incidentally, it follows that this absorbent compound must have a different structure from that of all its

derivatives; but as the gas gives an absorption-band at wave-length 2961, it is suggested that the absorbent compound is a hydrated form of sulphur dioxide formed according to the scheme—

$$(x-1)H_2O + H_2SO_3 \rightleftharpoons SO_2,xH_2O.$$

THE use of chains for power driving has increased greatly, and we note with interest from the *Engineer* for October 8 an account of a chain drive transmitting about 5000 horse-power in a hydro-electric plant on the Snake River in the State of Oregon. The chains connect the waterwheel shafts to the generator shaft, and the arrangement was designed to meet conditions imposed by financial considerations. These conditions necessitated the adaptation of generators designed for direct connection to waterwheels running at 225 revs. per minute under 50-ft. head, to the same wheels running at 160 revs. per minute under 20-ft. head. The generator is of 3600 kilowatts, three-phase, 60 cycles, and had to be operated at the intended speed. The problem was solved by changing the position of two waterwheel units, providing additional shafting, and driving the generator shaft from the two waterwheel shafts by driving chains and sprocket wheels. Each set of driving chains consists of four Morse silent chains, 22 in. wide, and transmits 2500 horse-power. This is believed to be the most powerful chain drive plant in the world, the nearest to it being that at Indianapolis, which drives a 1200 horse-power generator.

OUR ASTRONOMICAL COLUMN.

COMET 1915*d* (MELLISH).—A card from the Copenhagen Observatory informs us that the following elements and ephemeris have been calculated by Messrs. Braae and Fischer-Petersen for Mellish's comet from observations at the Yerkes Observatory on September 18 and the Lick Observatory on September 19 and 20:—

$$T = 1915 \text{ Oct. } 11{\cdot}933 \text{ M.T. Berlin.}$$

$$\left.\begin{aligned} \omega &= 108^\circ\ 33'{\cdot}16 \\ \Omega &= 72^\circ\ 50'{\cdot}17 \\ i &= 49^\circ\ 41'{\cdot}62 \end{aligned}\right\} 1915{\cdot}0$$

$$\log q = 9{\cdot}72054$$

M.T. Berlin.

A LARGE FIREBALL.—Mr. W. F. Denning writes:—"On the night of October 5 at 10h. 56m. Mrs. Fiammetta Wilson saw a large fireball from Portscatho, near Falmouth. It appeared in the N. by E. sky, its observed path being from 140°+68° to 126°+57°. A remarkable feature about the object was that it left a streak which remained visible for 17½ minutes, and underwent some curious transformations during the time it continued luminous. At first a straight band of glowing light, it gradually resolved itself into a large oval, which drifted slowly eastwards.

"The meteor must have been one of the most brilliant which has appeared for some time, and it is desirable to obtain further observations, both of the flight of the object and of the successive positions of the streak it left."

Mr. Arthur Mee sends us the following note upon the object:—

"A remarkable meteor was seen in south-west Wales on the evening of October 5. An observer at Mumbles says it appeared at seven minutes to eleven, and that the 'tail' retained its form for a minute and a half, and then gradually took the appearance of a hook, broadening as it did so, and finally fading away some seven minutes later. The meteor itself was so brilliant that it alarmed a dog and made it run indoors. An observer at Milford Haven says the appearance after the explosion of the meteor was that of a luminous cloud, 'a gigantic smoke-ring with wings.' It was first noticed in the zenith, and then gradually drifted in a north-easterly direction, becoming more diffuse, and finally disappearing soon after 11 o'clock. It was a bright, starry night, and the meteoric cloud was evidently self-luminous; the stars were seen quite clearly through it."

RECENT OBSERVATIONS OF VARIABLES.—One of four variable stars discovered by Dr. Silbernagel in 1907, since designated SS Aurigæ, belongs to the small class of long-period irregular variables of which U Geminorum is the best-known example. Almost from discovery it has received attention at Utrecht, where a large number of visual observations have been made by Prof. A. A. Nijland and Mr. van der Bilt (*Astr. Nach.*, 4814). Although most of the time it remains beyond visibility in the 10-in., twenty-five of its rather sudden accessions of lustre were followed during 1912–13. Of these, fourteen were "long" and eleven "short" maxima; correspondingly it was recorded brighter than 14·0m. for periods on the average of 14·6 and 8·2 days, attaining in the one case to 10·7m., in the other only reaching 11·0m. The mean curve for the "long" type of maximum almost precisely parallels that of U Geminorum, the latter being just one magnitude brighter. At Harvard the minimum brightness of SS Aurigæ has been measured as 15·9m., equivalent to 14·7m. in Prof. Nijland's system.

Mr. Torvald Köhl (*Astr. Nach.*, 4813) obtained further observations of 25, 1913, Ursæ Majoris during January–March of this year, from which the period of twenty-eight days gains additional weight.

A new variable star, 2, 1915, Cephei, has been found by M. Kostinsky, using the stereo-comparator (*Astr. Nach.*, 4809). The photographic magnitude increased by three units between November 29, 1911, and November 6, 1913, when it was 10·0m. M. Blazko has made confirmatory observations.

THE VICTORIAN OBSERVATORY.—The existence of this institution—better known as the Melbourne Observatory—is now definitely threatened. From Australian papers we learn that the State Astronomer, Mr. P. Baracchi, tendered his resignation last August after some thirty-nine years of Government service, the last fifteen years as successor to Mr Ellery. According to the *Age*, no successor is to be appointed, the State Government having decided to drop the work, thereby saving upwards of 4000*l.* annually. We trust some scheme of Commonwealth control will be evolved before it is too late.

THE PROPER MOTION OF A.G. WA. 5002.—In *Astr. Nach.*, No. 4814, Mr. R. J. Pocock, Nizamiah Observatory, Hyderabad, states that this star, No. 267 in Mr. van Maanen's recent list of proper-motion stars, has been photographed on two astrographic plates, neither of which shows any trace of proper motion.

FAMILY HISTORIES AND EUGENICS.

In the thirteenth bulletin (June, 1915) from the Eugenics Record Office (Cold Spring Harbour, Long Island, New York), Messrs. C. B. Davenport and H. H. Laughlin give precise directions for making "a eugenical family study." The general lines are similar to those of the records of family histories which Sir Francis Galton sought to initiate in Britain many years ago. Such a study, carefully made, is, the authors tell us, important to the individual, who may understand and guide himself better if he knows his hereditary assets and liabilities; important to society, which "can treat the delinquent individual more reasonably, more effectively, and more humanely, if it knows the 'past performance' of his germ-plasm"; important with a view to "vocational selection," the end of which is to get the right man in the right place; important for education, which should take some account of the inborn potentialities of the individual; and important, finally, in the selection of marriage-mates, or at least in avoiding obviously unfit unions.

The bulletin tells the inquirer how to construct his "family tree" when the facts have been secured, and how to make an "individual analysis." This rather formidable enterprise involves answering sixty questions as to life-history, and as to physical, mental, and temperamental traits. The framing of the questions embodies long experience, and even to put them to oneself is interesting. Drs. Hoch and Amsden supply an even more elaborate *questionnaire* as to mental and temperamental traits. It will be hard to discover any trait that this catechism leaves out. It begins by asking the victim "if his education is up to his opportunities," and it ends by asking in what he gets "his deepest satisfaction." The questions are much more penetrating than those of the census paper or the income-tax return, and some of them seem to demand for their truthful answer a rare degree of detachment. But the authors meet this objection by pointing out that the records are to be kept as confidential documents in the central bureau, and that one must not think too much of personal privacy when the welfare of the race is concerned. Certain it is that a scientific genealogy is worth working towards, and that this bulletin is a useful step in that direction—useful in educating public opinion and in giving critics something to work on. In this connection it may be doubted, for instance, whether it is a wise discretion to refrain from any attempt to differentiate in the recording of family data between heritable and non-heritable traits. It may also be asked whether there is not a distinct risk of developing a self-conscious pre-occupation about one's "traits"—that Herbert Spencer was always talking about—and a paralysing obsessional conviction of the fatalism of heredity, which is only one side of the case.

CHARACTER AND INTELLIGENCE.

The *British Journal of Psychology* has published as a monograph supplement (Cambridge University Press) the results of a research by Mr. Edward Webb on character and intelligence. The subjects of the inquiry were ninety-eight men students at a training college in 1912, ninety-six students at the same college in 1913, and four groups of schoolboys, amounting in all to 140. At the training college the prefects (second-year students), and at the schools the class-masters were utilised as judges, a pair of independent judges being employed in each case. Very careful instructions were given and detailed lists of qualities supplied. Examination results and experimental tests of intelligence were also used. All the assessments were ultimately translated into a scale of marks from +3 to −3. The "reliability coefficients" (correlations between the estimates of the same quality in the same individual by the two judges) were in many cases very low, the average being rather under 0·5, and nearly one-seventh of the qualities marked were rejected on the ground of unreliability. For those retained the average reliability coefficient is 0·55. The lowness of the "reliability coefficient" is held in part to be due to the care taken to secure independence between the estimates of the two judges. For intelligence-qualities the results are held to give a "strikingly thorough support" to the theory of a general factor. The deduced correlations of the general factor with the various estimates are discussed in detail, and give some interesting and unexpected results. Amongst the latter may be mentioned the fact that sense of humour, which has little correlation with the general factor, is fairly highly correlated with the estimates, the prefects' judgments being apparently biased by this quality. The character-qualities are discussed in the same way, and here again there is held to be evidence of a central factor, and this factor is in some close relation to "persistence of motives." This general factor markedly dominates all the correlations yielded by the estimates of moral qualities, the deeper social virtues, perseverance and persistence; also, negatively, qualities related to instability of the emotions and the lighter side of sociality.

SCIENCE IN THE WAR AND AFTER THE WAR.[1]

It is universally acknowledged that the outcome of the present war must be an entirely new chapter in human history and a point of fresh departure in social, economical, and intellectual life. Hence it is well to begin even now to take stock of our resources, to examine not only the reasons for our deficiencies but the directions of our reforms. Particularly are we concerned with the improved attitude which we shall have to take nationally with regard to all that study and knowledge which we call science and scientific research and invention. Hence an important matter is to consider the position of science in the war and after the war.

Scientific knowledge is the accumulation of exact information concerning the facts and laws of nature, and the scientific method is the process by which we gain it, viz., by experiment or observation and logical deduction therefrom.

The cardinal fact which lies at the basis of all this nature-study is that there is no finality in it. Its possibilities are infinite, and we can never touch bottom in all that there is to be known about the simplest objects or phenomena of nature.

Hence the very essence of scientific study is that the votary should himself make some advances. Merely to know what others have done or discovered may be necessary, but this alone does not make a scientific student. Accordingly the training required is that which imparts the power to make new knowledge, and the results must be judged by the degree to which it succeeds in so doing.

At this stage we may distinguish, however, two classes of workers. There are first those who are most interested in new facts or principles regardless of immediate utility, and, secondly, those who show ability in utilising this knowledge in so-called useful applications of science. The first class em-

[1] An introductory lecture delivered at University College, London, on October 6, by Prof. J. A. Fleming, F.R.S.

braces the purely scientific investigators, and the second the inventors.

The public is, unfortunately, apt to attach more importance to the inventions than to the investigations, regardless of the fact that there could be no applications if there were no knowledge to apply. This failure to recognise the value and unspeakable importance of a progressive disinterested study of nature is a characteristic British quality, and it is something very much more serious than a mere national trait or idiosyncrasy.

Philosophical students of politics have long recognised that all forms of government have their special defects, and democratic or representative Parliamentary government is no exception. One of the chief defects of the latter is that the men who gain the upper hand are too often the fluent or persuasive speakers or those who are skilled in managing public assemblies and masters in oratory and debate.

Hence, as Mr. F. S. Oliver points out in his very suggestive book, "Ordeal by Battle," in all countries where representative government prevails this type of leader exercises a considerable and predominant influence on public affairs. But with the professional speaker and politician an over-great importance attaches generally to phrases and to words. Success with them depends very much on how a thing is put, and the form of expression often overrules even the subject-matter itself. But the whole object of scientific work is the discovery of the truth, and not its obscuration. Therefore the ascertainment of fact or principle is in all this work of infinitely more value than the form of words in which it is expressed. Hence to the politician there is a certain uncongeniality about the scientific habit of mind, whilst the man of serious scientific training becomes at times impatient of the methods of the party politician, which have not facts at the back of them.

Accordingly the principal idea which it is necessary to instil into the public mind and drive home by every means is that our chief concern should be to bring the scientific method to bear upon all the affairs of the nation.

The second equally important truth is that the disinterested but systematic study of nature is of primary importance for national well-being. By disinterested study we mean pure scientific research not undertaken mainly for commercial reasons. Pope, I think, tells us that the proper study of mankind is man; but an even more important object of study for man is that of nature, and if we undertake that properly all other things in the way of applications will be added unto us. The point to notice, however, is that it is not everyone who possesses the necessary turn of mind for scientific investigation. There is a mysterious aptitude in some children for music, drawing, or other pursuits, and suitable training cultivates it. It is the same with the ability to discover or invent. Hence the primary duty of the nation with regard to its children is from the very earliest days to begin with them the study of nature, not in the repulsive form of learning things out of books, but by taking the child direct to the lap of Mother Nature and letting her teach the lessons about flowers, animals, stars, and earth structure.

All this, of course, means expenditure, but the nation has to learn this hard lesson, that education of the right kind cannot be given without wise and large outlay, and that there is nothing so expensive in the long run as cheap education. Another thing that has to be drilled into the public mind at all costs is that there are no short cuts to national efficiency or scientific pre-eminence.

The moment a deficiency is discovered, the tendency of the public is to cry out for some quick remedy; but quick remedies are very often quack remedies at best. We require, therefore, in the first place an entirely altered attitude of mind on the part of our public men, statesmen, and, above all, editors and managers of great daily newspapers towards scientific work, research, and teaching. We want a far greater appreciation of its supreme importance and of the attention that should be given to the cultivation of it under the guidance of expert leaders. The small degree to which genuine scientific work is appreciated, contrasted with mere sensational announcements not based on genuine discoveries or inventions, is seen in the treatment of scientific work by the daily Press, which, after all, only reflects the attitude of mind of the general public. Compare, for instance, the attention accorded before the war to politics, amusement, and fashion, and that accorded to accounts of scientific researches or lectures, in the principal daily papers. Worse still, some of them are apparently easily led to take up and boom perfectly unscientific but sensational announcements.

An illustration of this occurred not long ago in connection with a supposed great invention of a flying train. The scientific principle utilised was one discovered thirty years ago independently by Prof. Elihu Thomson and by me, and familiar for years to all electricians, viz. the repulsion exerted on electric conductors by a powerful alternating-current magnet. By this means the inventor proposed to raise a train off the rails and propel it, I think, at three hundred miles an hour. Every engineering student, however, knows well that the resistance to the motion of a train at high speed is largely air resistance, and that this increases very rapidly with the speed. Hence even if there were no rail or axle friction at all, an economical limit to the velocity is soon reached at which the cost of driving power becomes prohibitive.

The inventor ignored this important fact, and for a week at least the utmost nonsense was written in daily papers by journalists whose only qualification for the task was an exuberance of language and metaphor combined with an utter ignorance of scientific facts. New inventions or suggestions require careful, sympathetic, yet critical treatment, but the public are misled when imagination is allowed to run riot too soon. Nevertheless, even great discoveries or inventions, such as the Röntgen rays or wireless telegraphy, have been received with scepticism and their utility denied at first.

The daily Press, which has such immense influence on public opinion, should exercise wise guidance in these matters, aided by competent scientific opinion, yet with discrimination and care not to denounce novelty merely because it is new or strange.

Turning to the applications of science in the war, we can mention four chief departments of it under the headings: chemical, mechanical, electrical, and physical, which cover such appliances as high explosives, aeroplanes and dirigibles, submarines, wireless telegraphy, and range-finders. I shall not attempt to discuss the details of a fraction of all these applications, but just touch briefly on two departments which happen to have occupied my own attention during the vacation, viz. range-finders and wireless telegraphy from aeroplanes.

An extremely important matter in all war with projectiles is to ascertain the exact distance of the objective, whether it be ship or gun or building. The range of the projectile depends on the angle of elevation of the gun and the character of the ammunition and several other factors.

The proper setting of the gun can, of course, be determined by trial shots, but the larger the gun the more expensive this process, and the more necessary not to let the enemy know anything until a shot

or shell falls exactly where it can do most damage to him.

Range-finders have for their object to determine this distance by some optical appliance. They are divided into two classes: first, prism or base range-finders, and, secondly, subtend range-finders. We can explain the principle of these by reference to our eyes and the method by which we roughly judge the distance of an object. When we look at an object the optic axes of the eyes converge on it, and by long practice we are able to appreciate the inclination of the axes. The centres of the eyes are about 2½ in. apart. Hence we have a very short-based isosceles triangle, but we are enabled by our muscular sense to give a rough guess as to the angles at the base and practically to infer something about the length of the triangle. Again, we do it in another way by estimating the relative sizes of the image of known objects, such as a man or house or other thing which is formed on the retina. Another thing which assists us is the amount of detail we see in the object looked at.

The range-finders used in war are only more exact applications of the same principles. One of the most accurate is that of Profs. Barr and Stroud. This is a base or prism range-finder. It consists of a tube varying from half a metre to two metres, about 6 ft. in length. At the ends of this tube are two totally reflecting prisms, which receive rays from the object and send them down the tube. At each end of the tube is an object glass, which forms an image which is received on a peculiarly cut prism at the centre and by an eye-piece. The arrangement virtually forms a sort of double telescope corresponding to two eyes set 6 ft. apart. When the observer looks into the right eye-piece he sees a field of view which is divided into two parts, one produced by light coming into one object glass, and the other by that coming in at the other. If the object seen is a mast, say, of a ship, it appears broken in two parts. The observer can rectify or bring into agreement these two parts of the image by moving to or fro in the tube a thin prism. The position of this prism is read off on a scale seen with the left eye-piece. This scale shows the distance in yards of the object.

Thus on board our battleships a range-finder of this kind is placed in one of the fighting-tops on the masts, and the observer looking at a distant ship can in a few seconds move the prism, adjust the two parts of the image to agreement, and read off the range. He then sends down the range by telephone to the gun-layers. Thus in the battle of the Dogger Bank, and in that of the Falkland Islands, firing by our battleships began at about 17,000 or 18,000 yards. The range-finder would thus be continually sending down the ranges 20,000, 19,000, 18,000 yards, etc., and the gunners would keep the object vessel in sight and fire when the command was given as the known range of hitting was reached.

The same principle is applied in a smaller instrument for military use, called the Marindin range-finder, invented by Major Marindin, only in the latter instrument the means adopted for bringing the two parts of the field of view or image into agreement are by a movement of one of the prisms.

The Barr and Stroud range-finder is a very accurate instrument, and will determine ranges up to 20,000 yards, or about 12 miles, with an accuracy of 50 to 100 yards.

In the next place there are range-finders called subtend range-finders, which depend on the measurement of the size of an image of a known object. When we look at an object either with the eye or with a telescope at different distances, it appears to be smaller the farther away we are from it. In the case of the eye we have no means of measuring accurately this variation in size except by comparing the apparent size of the distant object with some near object the size of which is known. Hence judging distance by the eye requires long training, as all sportsmen, sailors, and travellers know.

Moreover, we are apt to be deceived as to the apparent size. Ask anyone, for instance: How large appears the full moon? Many people would say, As large as a shilling—meaning that it has the same apparent angular magnitude as a shilling seen at 10 ins. or 1 ft., which is the usual distance we hold a book or paper when reading.

But now, if you try the experiment, you will find that the full moon is covered by a very small pencil, like a pocket-book or dance-programme pencil, held at 10 in. from the eye. In scientific language, the apparent size of the moon is about half a degree, which means that it is covered by an object 1/10th in. in diameter held 1 ft. from the eye.

A man 6 ft. high would subtend the same angle at a distance of 720 ft. Hence you can tell the distance of a man by ascertaining the distance at which an object of known size, say a pencil, must be held so as just to cover his height. An ordinary pencil ¼ in. in diameter held horizontally at arm's length (=2 ft.) would just cover a man 5 ft. 8 in. high at a distance of 544 ft., or 181 yd. The subtend range-finder works on the principle of measuring the angular magnitude of the object. One way of doing this is to place in the focus of the eyepiece a plate of glass with divisions ruled on it with a diamond. If we know how many divisions are covered by an object of known height at a known distance, we can tell the distance of any other object of known height.

It is very seldom, however, that we do know the exact height of the object, and, moreover, it is very difficult to count up accurately many very small divisions ruled on glass when the object seen is at all dark.

During the vacation I have been turning attention to methods for overcoming some of these difficulties. As these inventions are being submitted to the Ministry of Munitions, I do not think it desirable to go into details as to the methods, but I will tell you the results. I have invented three forms of range-finder—one which is an improved subtend range-finder with which I can find the distance of any object the dimensions of which are known, whether height or width, or any part of it. Also I have invented methods for using two such instruments to measure the distance of objects the dimensions of which are not known. In the second place, I have invented a simple form of base range-finder which measures what is called in astronomy the parallax of any distant object, and hence determines its distance. In the third place, I have devised a simple form of depression or elevation angle meter by means of which the height of any hill, and also the distance of any object from it, or from an elevated position, can be determined by an observer standing at the top of the hill, provided that he can also see two marks placed at the base in line with the point of observation on the hill and at a known distance apart. These instruments are simple and inexpensive to construct, and give an accuracy of measurement quite sufficient to direct rifle or artillery fire or bomb throwing in trenches. One great advantage of my range-finder is that it can be used with a periscope from the bottom of a trench so that the observer need not be exposed at all, but can determine the distance of the enemy's trench by observation on any post of a wire entanglement or stick or rock or anything with a sharp outline. Another principle which may be applied in making a range-finder, which I have also done in my instruments, is to observe the variation in

the size of an object as seen in a small telescope by moving away from it a certain distance. Thus, suppose that a man was seen at a distance of 200 yd., or 600 ft., then his apparent height would be covered by the width of a pencil held about 2 ft. from the eye. Suppose the observer were to approach to half that distance or move in 300 ft., then the apparent size of the man would be doubled. If, however, the man were a mile away, then moving towards him 100 yd. would only increase his apparent height by about 6 per cent. Hence we can determine the distance of an object by finding out how much the apparent size is increased when we move in towards it 100 yd. or any assigned distance.

Another marvellous application of science in war is that of wireless telegraphy in connection with aeroplanes and airships as a means of scouting and rapid communication of intelligence.

The difficulties connected with it are, however, considerable, and it has greater limitations than the uninitiated would suppose.

In the case of aeroplanes the first of these is the weight of the apparatus. The military aeroplane is already loaded to its fullest extent. In addition to the pilot and observer and the bomb ammunition, it carries in nearly all cases some gun equipment. Hence any wireless apparatus must be made as light and compact as possible. A wireless transmitter of the so-called spark type involves three elements: (i) some source of electromotive force such as a battery or dynamo, (ii) an induction coil or transformer for creating a high electric potential or pressure, and (iii) some form of condenser or Leyden jar which is charged and then discharged across a spark gap, thus creating rapid movements of electricity called electric oscillations. These oscillations are then caused to create others in a long wire called the aerial wire.

In the case of aeroplanes and airships the source of electromotive force is generally a small dynamo or alternator, which is coupled to the engine, and the voltage or pressure is raised to 30,000 volts or so by a small transformer sealed up in oil in a box. The condenser consists of metal plates sandwiched between sheets of glass or ebonite, and the spark balls between which the spark passes are also enclosed. The weight of the whole apparatus has to be kept below 100 lb., and such apparatus has been designed having a weight of not more than 30 lb. The French use a set weighing about 70 lb. One of the difficulties is to dispose the aerial wire conveniently and safely. It is sometimes made of aluminium and stretched on insulators carried by light supports on the wings, but the difficulty is to obtain in this way sufficient length. One plan adopted is to coil the wire on a reel, which the observer can uncoil and let it float out behind the aeroplane.

The wire must be connected to the reel by a safety catch so as to be released at once if it catches in trees or buildings. By this means an aerial wire of 100 ft. in length can be employed. The observer has near his hand a key by which he controls the spark discharges and so sets up in the aerial wire groups of electric oscillations which create electric waves in the æther, and signal the message in Morse code.

In this manner there is not much difficulty in equipping aeroplanes with transmitters which will send messages 30 miles or so to a corresponding earth station.

These latter are the military portable motor-car or pack stations, the details of which were described in a lecture given here last year on "Wireless Telegraphy in War."

The receiving arrangements used on aeroplanes comprise a head-telephone which is worn by the observer associated with some simple form of detector such as a carborundum crystal, aided by which the observer hears the signals sent to him in Morse code as long and short sounds in the telephone.

The noise of the aeroplane engine and that of the rush of air renders this method of aural reception a matter of great difficulty, especially as the messages must be sent in secret code, and the observer must therefore hear every letter distinctly if the message is to be intelligible. Great efforts have been made to devise methods of reception which shall appeal to the eye by a visual signal rather than to the ear, but the exceedingly small electric currents set up in the aerial wire by the arriving waves make this a matter of extreme difficulty, and the problem has not yet been completely solved. There is then the difficulty caused by "jamming." If the signals from an aeroplane are picked up by a hostile station, this latter at once sends out powerful but unmeaning signals the object of which is to blur and drown out the reception or sending of signals by this aeroplane. Moreover, the sending of wireless signals by an aeroplane reveals its presence to hostile earth stations before it can be seen by the eye.

Hence wireless telegraphy may be a means of revealing the enemies' scouts, and it involves a certain kind of war in the æther as well as war in the air.

In the case of airships there are other difficulties as well, and it is interesting to note that there are special difficulties in connection with Zeppelins. These aerial monsters are, as everyone knows, constructed with a framework of aluminium, containing in its interior the eighteen or twenty balloons inflated with hydrogen. Now as we rise upwards in the air the electric potential increases rapidly, and if a conducting body at a height gives off water drops or products of combustion, it is rapidly brought to the potential of the air at the place where it is. In the case of Zeppelins this equalisation is no doubt brought about by the escape of products of combustion produced by the engines. When the conducting body is brought down suddenly to earth again, there may be a great difference of potential between it and the objects on the earth. If it is a good conductor, a spark may pass, and if it is, as in the case of a Zeppelin, a conducting body containing a highly inflammable gas, leakage of which cannot altogether be prevented, this spark may cause an explosion and destruction of the airship. Again, the violent electric oscillations created in all metal objects near powerful radiotelegraphic apparatus may cause sparks to jump between metal parts, and hence may inflame a hydrogen leak.

It has therefore been recognised that there are special electrical difficulties in connection with the working of wireless on rigid airships with metal frames and also in connection with the use of spark apparatus. However carefully the actual working spark is enclosed there is always risk of induced sparks.

There is room, therefore, yet for much research and experimenting in connection with the use of wireless telegraphy on aeroplanes and airships, and the practical problems are by no means completely solved.

This leads to the consideration of the methods we have adopted for dealing with these and all other suggestions of the same kind of the nature of war inventions.

The Royal Society appointed certain committees at an early stage in the war to deal with engineering or mechanical and with chemical inventions. These committees were constituted secret committees, and none of the fellows except the council and the small number of the appointed fellows were allowed even to know the names of the members. The ostensible reason for this unusual secrecy was that the committees should not be inundated with correspondence

from eager inventors and that their work was confidential, but this argument is scarcely valid because the names of the members of other inventions committees, such as those afterwards appointed by the Admiralty and the Ministry of Munitions, were made public. The publication of the names of members in no way necessitates the publication of information as to their work. In the formation of such committees the important qualification should be not merely scientific or theoretical learning, but sufficient practical knowledge of the matters considered.

The men whose opinions are valuable on war inventions are the men who have to use them, namely, experienced military and naval officers. Again, the value of an invention can usually only be estimated by a practical trial, and this means expenditure. It is an almost impossible matter to judge of an invention merely from a written description. An idea may be old or a method may be familiar, and yet it may be carried out in detail in such a manner as to have great practical value under certain conditions. The ability to form a correct judgment of an engineering invention requires a very wide experience, since it is not easy to appreciate the good points or anticipate the defects of an invention or suggestion or idea which has not been put to the test of practice. Nevertheless, the experts appointed by the Ministry of Munitions are doing valuable work in sifting out the useful ideas from the hundreds already submitted to them.

It is beyond any doubt that this war is a war of engineers and chemists quite as much as of soldiers.

The 42-cm. Krupp gun which smashed in a few days the fortifications of Liège, Namur, and Antwerp, which were confidently expected to hold out for months, is only a piece of heavy engineering. The complete gun weighs 87 tons, and the foundations or carriage 37 tons. Two hundred men are necessary to erect and work each gun, which requires twelve railway wagons for its transport and is composed of 172 parts. It takes twenty-five to twenty-six hours to erect in place. The projectile or shell weighs 8 cwt., and is 5′ 4″ long and 16½″ diameter. It is fired electrically from a distance of about a quarter of a mile, and each shot costs 550*l*. The range at which the Liège forts were destroyed was fourteen miles. The mere transport and erection of this gun, let alone its manufacture, demands engineering knowledge of a special kind. It is the same with smaller arms. The rifle, except as a support for a bayonet, has almost become obsolete in face of the machine gun.

To win this war we have to achieve engineering feats. The mammoth howitzer, the great armoured triple-engined aeroplane, and the quick-firing machine guns are all products of the engineer's workshop, and the pivot round which all Germany's maleficent power turns is Krupp's works at Essen, and the chemical and ammunition factories in Westphalia. The knock-out blow will be given at those points, and they must be reached through the air if trench work proves too slow.

But in addition to the concentration of engineering knowledge and skill on the problems of the war, we have to think as well of what will come after. What is required is not merely opinions on inventions already made, but the proper organisation of inventive power and scientific research to bring about new and useful results. This is only to be achieved by bringing to bear adequate combined inventive or scientific power on definite problems which are not too far removed from practical possibilities.

We have as yet made scarcely any progress in the creation of a disciplined army of scientific workers which shall embrace all the abilities in the Empire. We are still in the stage which by comparison with an army is that of a mob of civilians equipped for war with shot guns and sticks.

One reason for this, I think, is because our chief scientific body, the Royal Society, has not taken upon itself more the function of guiding and assisting the general direction of research and invention.

The real function of the Royal Society should be to organise, direct, influence, assist, and promote scientific research, and to do it by an efficient organisation embracing the whole of its fellows. It represents, or should represent, the very best ability in all departments of scientific knowledge, and it should be organised into grand committees of subjects, as suggested by Prof. Armstrong, on one or more of which every fellow should have his place. The work of these grand committees should be to guide and instigate research in their own departments, to organise general discussions on leading questions in the manner undertaken of late years by the British Association, and to help to direct towards common and important ends the powers of scientific investigation in our universities and colleges.

The special and technical societies provide the facilities required for the reading of papers. A paper on physics, chemistry, or engineering as a rule receives better discussion and criticism if read at the Physical, Chemical, or Engineering Societies than at the Royal Society, and the discussion on a paper, if proper time and notice are given, is often quite as valuable as the paper itself. Although the individualistic method of research in which each scientific worker takes up whatever kind of research he pleases has produced good results in the past and is in agreement with our national characteristics, it is a serious question whether we shall not have to put limits to it in the future. The problems which await solution require in many cases combined or co-operative research. One of the most useful improvements in the proceedings of our learned societies would be the devotion of more time to well-organised and predetermined subjects of debate with the object of advancing knowledge at the boundaries of cognate sciences.

This applies to the purely scientific problems, as well as to the problems of industrial research. It must be remembered that, after this war is over, in a military sense we shall immediately commence another war of a different kind, in which the weapons will not be bullets and shells, but our national powers of invention, scientific research, commercial organisation, manufacturing capabilities, and education, and these will be pitted against those of a highly organised Germany determined to win back in commerce by any and every means, fair or foul, that which has been lost in war.

That commercial and industrial war will be waged by our enemies with the same ruthlessness and neglect of all scruples as their military operations. We have said good-bye now and for ever to those easy-going amateur British methods which have held us in the past. What we require is to obtain a higher percentage efficiency in all our operations. We have to attain larger and better results in education, scientific research, and industrial work to increase our national output in every way.

We have been buying dyes, chemicals, optical instruments, and drugs from Germany, glass from Austria, arc light carbons, electric machinery, and a hundred other things we have no need to buy, and the reason is that we have been shirking the effort and research necessary to make them as cheaply or as well at home. But the England with a national debt of 2000–3000 millions sterling will be a different kind of place to live in from the England of the year before last, and we shall have to adapt ourselves to the new conditions by new methods of work.

One of the most important of these, I venture to think, is the extension of co-operative research, both scientific and industrial. In the case of industrial work manufacturers are afraid of making their wants and difficulties known lest the mere statement of them should enable a British rival to find a solution and get ahead. It is necessary to appreciate, however, that rivalry between British manufacturers is not nearly such a serious matter as the competition of Germany with all of them will become, and that British manufacturers will have to stand shoulder to shoulder to meet the common foe. German firms do not hesitate to pool their knowledge if it enables Germany to get ahead of other nations, and British trades will therefore have to meet this organisation by one of a similar kind. In the same manner I have long been convinced that far greater advances might be made in purely scientific research in many departments of knowledge if we were to adopt more extensively the custom of associated work. I mean by this the formation of committees of workers, not too large for expeditious decisions, but charged with the duty of investigating certain formulated problems. It is in this respect that our learned societies might do so much more than they do. The proceedings of these societies are mostly a record of isolated, disconnected pieces of work of very different scientific value. But if properly organised discussion were brought to bear on the question, it would be possible to induce investigators of reputation and ability to associate themselves more in conjoint work to the great advantage of our common knowledge. The learned societies should therefore fulfil to the adult and experienced investigator the same function which the professor or teacher should fulfil to his research students, viz., supply them with suggestions for lines of research to stimulate thought and invention.

It is quite certain that we shall have to organise in this way to a far higher degree than we have yet done what may be called the strategy of research, and that the learned societies should act in some capacity like the great general staff of an army towards the subordinate generals and corps commanders. We require therefore to get on to the councils of our learned and technical societies and into their presidential chairs not merely men eminent for their private researches, but men of large ideas with organising abilities and inspirational power. If we do not do this, then, although by a lavish sacrifice of life and treasure we may win, as we are determined to do, in the military and naval operations, we shall in the long run be hopelessly defeated in that slower but none the less deadly scientific and commercial competition which will follow upon the cessation of actual hostilities.

THE BRITISH ASSOCIATION.

SECTION D.

ZOOLOGY.

OPENING ADDRESS[1] BY PROF. E. A. MINCHIN, M.A., HON. PH.D., F.R.S., PRESIDENT OF THE SECTION.

The Evolution of the Cell.

I PROPOSE in this address to deal with an aspect of cytology which appears to me not to have received as yet the attention which it deserves, namely, the evolution of the cell and of its complex organisation as revealed by the investigation of cytologists. Up to the present time, the labours of professed cytologists have been directed almost entirely towards the study of the cell in its most perfect form as it occurs in the Metazoa and the higher plants. Many cytologists appear, indeed, to regard the cell, as they know it in the Metazoa and Metaphyta, as the beginning of all things, the primordial unit in the evolution of living beings. For my part I would as soon postulate the special creation of man as believe that the metazoan cell, with its elaborate organisation and its extraordinarily perfected method of nuclear division by karyokinesis, represents the starting-point of the evolution of life. So long, however, as the attention of cytologists is confined to the study of the cells building up the bodies of the higher animals and plants, they are not brought face to face with the stages of evolution of the cell, but are confronted only with the cell as a finished and perfected product of evolution, that is to say, with cells which, although they may show infinite variation in subordinate points of structure and activity, are nevertheless so fundamentally of one type that their plan of structure and mode of reproduction by division can be described in general terms once and for all in the first chapter of a biological text-book or in the opening lecture of a course of elementary biology.

One of the most striking features of the general trend of biological investigation during the last two decades has been the attention paid to the Protista, that vast assemblage of living beings invisible, with few exceptions, to the unassisted human vision, and in some cases minute beyond the range of the most powerful microscopes of to-day. The study of the Protista has yielded results of the utmost importance for general scientific knowledge and theory. The morphological characteristic of the Protista, speaking generally, is that the body of the individual does not attain to a higher degree of organisation than that of the single cell. The exploitation, if I may use the term, of the Protista, though still in its initial stages, has already shown that it is amongst these organisms that we have to seek for the forms which indicate the evolution of the cell, both those lines of descent which lead on to the cell as seen in the Metazoa and Metaphyta, as well as other lines leading in directions altogether divergent from the typical cell of the text-book. We find in the Protista every possible condition of structural differentiation and elaboration, from cells as highly organised as those of Metazoa, or even in some cases much more so, back to types of structure to which the term cell can only be applied by stretching its meaning to the breaking-point.

It is impossible any longer to regard the cell as seen in the Metazoa and as defined in the text-books as the starting-point of organic evolution. It must be recognised that this type of cell has a long history of evolution behind it, which must be traced out, so far as the data permit. The construction of phylogenies and evolutionary series is, of course, purely speculative, since these theories relate to events which have taken place in a remote past, and which can only be inferred dimly and vaguely from such fragments of wreckage as are to be found stranded on the sands of the time in which we live. All attempts, therefore, to trace the evolution of the Protista must be considered as purely tentative at present. If I venture upon any such attempt, it is to be regarded as indicating a firm belief on my part that the evolution of the cell has taken place amongst the Protista, and that its stages can be traced there, rather than as a dogmatic statement that the evolution has taken place in just the manner which seems to me most probable.

Before, however, I can proceed to deal with my main subject, it is absolutely necessary that I should define clearly the sense in which I propose to use certain terms, more especially the words "cell," "nucleus," "chromatin," "protoplasm," and "cyto-

[1] Abridged by the author.

plasm." Unless I do so, my position is certain to be misunderstood, as, indeed, it has been already by some of my critics.

The term cell was applied originally to the protoplasmic corpuscles building up the bodies of the Metazoa and Metaphyta, each such corpuscle consisting of a minute individualised mass of the living substance and containing a nucleus. Hence a complete cell is made up of two principal parts or regions, the nucleus and the remainder of the protoplasmic body, termed the cytoplasm. By some authors the term protoplasm is restricted to the cytoplasmic portion of the cell, and protoplasm is then contrasted with nucleus; but it is more convenient to consider the whole cell as composed of protoplasm divided into two regions, nucleus and cytoplasm.

We come now to the consideration of the body termed the nucleus, which undoubtedly possesses an importance in the life and functions of the cell far greater than would be inferred from the name given to it. I have described in general terms the typical nucleus of the text-books, as found commonly in the cells that build up the bodies of ordinary animals and plants. The minutiæ of the details of structure and arrangement of the constituent parts may vary infinitely, but the type remains fairly constant. When we come, however, to the nuclei of the Protista, such pronounced modifications and variations of the type are met with that a description in general terms is no longer possible. I will direct attention now only to one point. In the protist cell the chromatin is not necessarily confined to the nucleus, but may occur also as extranuclear grains and fragments, termed chromidia, scattered through the protoplasmic body; and the chromatin may be found only in the chromidial condition, a definite nucleus being temporarily or permanently absent.

The essential part of the nucleus is the chromatin, and the other structural constituents of the nucleus, namely, membrane, framework, and plastin or nucleolar bodies, are to be regarded as accessory components built up round, or added to, the primary nuclear material, the chromatin. Even with regard to the nuclei of Metazoa it is maintained by Vejdovsky that at each cell-generation the entire nucleus of the daughter-cell is produced from the chromosomes alone of the mother-cell. The simplest body which can be recognised as a nucleus, distinct from the chromidia scattered without order or arrangement throughout the protoplasmic body, is a mass of chromatin or a clump of chromatin-grains supported on a framework and lodged in a special vacuole in the cytoplasm.

This brings me to a point which I wish to emphasise most strongly, namely, that the conception of a true cell-nucleus is essentially a structural conception. A nucleus is not merely an aggregation of chromatin; it is not simply a central core of some chemical substance or material differing in nature from the remainder of the protoplasm. The concepts "nucleus" and "chromatin" differ as do those of "table" and "wood." Although chromatin is the one universal and necessary constituent entering into the composition of the cell-nucleus, a simple mass of chromatin is not a nucleus. A true nucleus is a cell-organ, of greater or less structural complexity, which has been elaborated progressively in the course of the evolution of the cell; it is as much an organ of the cell as the brain is an organ of the human body. As a definite cell-organ, it performs in the life and economy of the cell definite functions. As an organ of the cell, however, it has no homologue or analogue in the body of the multicellular animals or plants; there is no organ of the human body, taken as a whole, similar or comparable to the nucleus of the cell.

The foregoing brief consideration of the nucleus leads me now to discuss in more detail the nature and properties of the essential nuclear substance, the so-called chromatin. To define, or characterise adequately, this substance is a difficult task. The name chromatin is derived from the fact that this substance has a peculiar affinity for certain dyes or stains, so that when a cell is treated with the appropriate colouring reagents—with so-called nuclear stains—the chromatin in the nucleus stands out sharply, by reason of being coloured in a different manner from the rest of the cell. In consequence, the statement is frequently made, in a loose manner and without reflection, that chromatin is recognised by its staining reactions, but in reality this is far from being true. When a preparation of an ordinary cell is made by the methods of technique commonly in use, the chromatin is recognised and identified by its position in a definite body with characteristic structure and relations to the cell as a whole, namely, the nucleus, and this is equally true whether the chromatin has been stained or not. Any so-called chromatin-stain colours many bodies which may occur in a cell besides the chromatin, and it may be necessary to try a great many different stains before a combination is found which will differentiate a given cytoplasmic enclosure from a true chromatin-grain by its colour-reactions. The so-called volutin-grains, for example, which are found commonly in the cytoplasm of many protists, are identified by the fact that they have a stronger affinity for "chromatin-stains" than chromatin itself.

What, then, is the true criterion of the chromatin-substance of living organisms? From the chemical point of view the essential substance of the cell-nucleus would appear to be characterised by a complexity of molecular structure far exceeding that of any other proteins, as well as by certain definite peculiarities. Especially characteristic of chromatin is its richness in phosphorus-compounds, and it stands apart also from other cell-elements in its solvent reactions, for example, resistance to peptic digestion. How far these features are common, however, to all samples of chromatin in all types of living organisms universally, cannot, I think, be stated definitely at present; at any rate, it is not feasible for a cytologist of these days to identify a granule in a living organism or cell as chromatin solely by its chemical reactions, although it is quite possible that at some future time purely chemical tests will be decisive upon this point—a consummation devoutly to be wished.

The only criterion of chromatin that is convincing to the present-day biologist is the test of its behaviour, that is to say, its relations to the life, activity, and development of the organism. I may best express my meaning by an objective example. If I make a preparation of *Arcella vulgaris* by suitable methods, I see the two conspicuous nuclei and also a ring of granules lying in the cytoplasm, stained in the same manner as the chromatin of the nuclei. Are these extranuclear granules to be regarded also as chromatin? Yes, most decidedly, because many laborious and detailed investigations have shown that from this ring of granules in Arcella nuclei can arise, usually termed "secondary" nuclei for no other reason than that they arise *de novo* from the extranuclear chromatin and quite independently of the "primary" nuclei. The secondary nuclei are, however, true nuclei in every respect, as shown by their structure, behaviour, and relations to the life-history of the organism; they may fuse as nuclei of gametes (pronuclei) in the sexual act, and they become, with or without such fusion, the primary nuclei of future generations of Arcella; they then divide by karyokinesis, when the organism reproduces itself in the ordinary way by fission, and are replaced in their

turn by new secondary nuclei at certain crises in the life-history. In view of these facts, it can be asserted without hesitation that the ring of staining granules in Arcella is composed of, or at least contains, true chromatin-grains, extranuclear chromatin for which R. Hertwig's term chromidia is now used universally.

Having now defined or explained, as well as I am able, the terms of which I am about to make use, I return to my main theme, the cell and its evolution. To summarise the points already discussed, a typical cell is a mass of protoplasm differentiated into two principal parts or regions, the cytoplasm and the nucleus, or, it may be, two or more nuclei. The cytoplasm may or may not contain chromatin-grains in addition to other enclosures, and may possess cell-organs of various kinds. The nucleus, highly variable in minute structure, possesses one invariable constituent, the chromatin-material in the form of grains and masses of various sizes.

The cell, therefore, in its complete and typical form, is an organism of very considerable complexity of structure and multiplicity of parts. The truth of this proposition is sufficiently obvious even from simple inspection of the structural details revealed by the microscope in cells in the so-called "resting condition," but still more so from a study of their activities and functions. The vital processes exhibited by the cell indicate a complexity of organisation and a minuteness in the details of its mechanism which transcend our comprehension and baffle the human imagination, to the same extent as do the immensities of the stellar universe. If such language seems hyperbolic, it is but necessary to reflect on some of the established discoveries of cytology, such as the extraordinary degree of complication attained in the process of division of the nucleus by karyokinesis, or the bewildering series of events that take place in the nuclei of germ-cells in the processes of maturation and fertilisation. Such examples of cell-activity give us, as it were, a glimpse into the workshop of life and teach us that the subtlety and intricacy of the cell-microcosm can scarcely be exaggerated.

On the assumption that an organism so complex and potent was not created suddenly, perfect and complete as it stands, but arose, like all other organisms, by progressive evolution and elaboration of some simpler form and type of structure, it is legitimate to inquire which of the various parts of the cell are the older and more primitive and which are more recent acquisitions in the course of evolution. The evolution of the cell may be discussed as a morphological problem of the same order as that of the phylogeny of any other class or phylum of living beings, and by the same methods of inquiry.

The problem of cell-evolution may be attacked, beginning with the consideration of the primary structural differentiation of the typical cell, the distinction of nucleus, or rather chromatin, and cytoplasm.

Since no concrete foundation can be found for the view that cytoplasm and chromatin have a common origin in the evolution of living things, we are brought back to the view that one of them must have preceded the other in phylogeny.

For my part, I am unable to accept any theory of the evolution of the earliest forms of living beings which assumes the existence of forms of life composed entirely of cytoplasm without chromatin. All the results of modern investigations into the structure, physiology, and behaviour of cells, on the one hand, and of the various types of organisms grouped under the Protista, on the other hand—the combined results, that is to say, of cytology and protistology—appear to me to indicate that the chromatin-elements represent the primary and original living units or individuals, and that the cytoplasm represents a secondary product. I will summarise briefly the grounds that have led me to this conviction, and will attempt to justify the faith that I hold; but first I wish to discuss briefly certain preliminary considerations which seem to me of great importance in this connection.

It is common amongst biologists to speak of "living substance," this phrase being preceded by either the definite or the indefinite article—by either "the" or "a." If we pause to consider the meaning of the phrase, it is to be presumed that those who make use of it employ the term "substance" in the usual sense to denote a form of matter to which some specific chemical significance can be attached, which could conceivably be defined more or less strictly by a chemist, perhaps even reduced to a chemical formula of some type. But the addition of the adjective "living" negatives any such interpretation of the term "substance," since it is the fundamental and essential property of any living being that the material of which it is composed is in a state of continual molecular change and that its component substance or substances are inconstant in molecular constitution from moment to moment. When the body of a living organism has passed into a state of fixity of substance, it has ceased, temporarily or permanently, to behave as a living body; its fires are banked or extinguished. The phrase "living substance" savours, therefore, of a *contradictio in adjecto*; if it is "living" it cannot be a "substance," and if it is a "substance" it cannot be "living."

As a matter of fact, the biologist, when dealing with purely biological problems, knows nothing of a living substance or substances; he is confronted solely by living individuals, which constitute his primary conceptions, and the terms "life" and "living substance" are pure abstractions. Every living being presents itself to us as a sharply limited individual, distinct from other individuals and constituting what may be termed briefly a microcosmic unit, inasmuch as it is a unity which is far from being uniform in substance or homogeneous in composition, but which, on the contrary, is characterised by being made up of an almost infinite multiplicity of heterogeneous and mutually interacting parts. We recognise further that these living individuals possess invariably specific characteristics; two given living individuals may be so much alike that we regard them as of the same kind or "species," or they may differ so sharply that we are forced to distinguish between them specifically. Living beings are as much characterised by this peculiarity of specific individuality as by any other property or faculty which can be stated to be an attribute of life in general, and this is true equally of the simplest or the most complex organisms; at least we know of no form of life, however simple or minute, in which the combined features of individuality and specificity are not exhibited to the fullest extent.

The essential and distinctive characteristic of a living body of any kind whatsoever is that it exhibits while it lives permanence and continuity of individuality or personality, as manifested in specific behaviour, combined with incessant change and lability of substance; and further, that in reproducing its kind, it transmits its specific characteristics, with, however, that tendency to variability which permits of progressive adaptation and gradual evolutionary change. It is the distinctively vital property of specific individuality combined with "stuff-change" (if I may be allowed to paraphrase a Teutonic idiom) which marks the dividing line between biochemistry and biology. The former science deals with substances which can be separated from living bodies, and for the chemist specific properties are associated

with fixity of substance; but the material with which the biologist is occupied consists of innumerable living unit-individuals exhibiting specific characteristics without fixity of substance. There is no reason to suppose that the properties of a given chemical substance vary in the slightest degree in space or time; but variability and adaptability are characteristic features of all living beings. The biochemist renders inestimable services in elucidating the physico-chemical mechanisms of living organisms; but the problem of individuality and specific behaviour, as manifested by living things, is beyond the scope of his science, at least at present. Such problems are essentially of distinctively vital nature, and their treatment cannot be brought satisfactorily into relation at the present time with the physico-chemical interactions of the substances composing the living body. It may be that this is but a temporary limitation of human knowledge prevailing in a certain historical epoch, and that in the future the chemist will be able to correlate the individuality of living beings with their chemico-physical properties, and so explain to us how living beings first came into existence; how, that is to say, a combination of chemical substances, each owing its characteristic properties to a definite molecular composition, can produce a living individual in which specific peculiarities are associated with matter in a state of flux. But it is altogether outside the scope and aim of this address to discuss whether the boundary between biochemistry and biology can be bridged over, and if so, in what way. I merely wish to emphasise strongly that if a biologist wishes to deal with a purely biological problem, such as evolution or heredity, for example, in a concrete and objective manner, he must do so in terms of living specific individual units. It is for that reason that I shall speak, not of the chromatin-substance, but of chromatinic elements, particles or units, and I hope that I shall make clear the importance of this distinction.

To return now to our chromatin; I regard the chromatinic elements as being those constituents which are of primary importance in the life and evolution of living organisms mainly for the following reasons: the experimental evidence of the preponderating physiological *rôle* played by the nucleus in the life of the cell; the extraordinary individualisation of the chromatin-particles seen universally in living organisms, and manifested to a degree which raises the chromatinic units to the rank of living individuals exhibiting specific behaviour, rather than that of mere substances responsible for certain chemico-physical reactions in the life of the organism; and last, but by no means least, the permanence and, if I may use the term, the immortality of the chromatinic particles in the life-cycle of organisms generally. I will now deal with these points in order.

The results obtained by physiological experiments with regard to the functions of the nuclear and cytoplasmic constituents of the cell are now well known and are cited in all the text-books. It is not necessary, therefore, that I should discuss them in detail. I content myself with quoting a competent and impartial summary of the results obtained:—

"A fragment of a cell deprived of its nucleus may live for a considerable time and manifest the power of co-ordinated movements without perceptible impairment. Such a mass of protoplasm is, however, devoid of the powers of assimilation, growth, and repair, and sooner or later dies. In other words, those functions that involve destructive metabolism may continue for a time in the absence of the nucleus; those that involve constructive metabolism cease with its removal. There is, therefore, strong reason to believe that the nucleus plays an essential part in the constructive metabolism of the cell, and through this is especially concerned with the formative processes involved in growth and development. For these and many other reasons . . . the nucleus is generally regarded as a controlling centre of cell-activity, and hence a primary factor in growth, development, and the transmission of specific qualities from cell to cell, and so from one generation to another.[2]

I have mentioned already in my introductory remarks that the only trustworthy test of chromatin is its behaviour, and the whole of modern cytological investigation bears witness to the fact that the chromatinic particles exhibit the characteristic property of living things generally, namely, individualisation combined with specific behaviour. In every cell-generation in the bodies of ordinary animals and plants the chromatin-elements make their appearance in the form of a group of chromosomes, not only constant in number for each species, but often exhibiting such definite characteristics of size and form, that particular, individual chromosomes can be recognised and identified in each group throughout the whole life-cycle. Each chromosome is to be regarded as an aggregate composed of a series of minute chromatinic granules or chromioles, a point which I shall discuss further presently.

Even more remarkable than the relation of the chromosomes to cell-reproduction is their behaviour in relation to sexual phenomena. In the life-cycles of Metazoa the sexual act consists of the fusion of male and female pronuclei, each containing a definite and specific number of chromosomes, the same number usually, though not always, in each pronucleus. It has been established in many cases, and it is perhaps universally true, that in the act of fertilisation the male and female chromosomes remain perfectly distinct and separate in the synkaryon or nucleus formed by the union of the two pronuclei, and, moreover, that they continue to maintain and to propagate their distinct individuality in every subsequent cell-generation of the multicellular organism produced as a result of the sexual act. In this way, every cell of the body contains in its nucleus distinct chromatinic elements which are derived from both male and female parents and which maintain unimpaired their distinct and specific individuality through the entire life-cycle. This distinctness is apparent at least in the germ-cell-cycle of the organism, but may be obscured by secondary changes in the nuclei of the specialised tissue-cells.

Only in the very last stage of the life-cycle do the group of male and female chromosomes modify their behaviour in a most striking manner. In the final generation of oogonia or spermatogonia, from which arise the oocytes and spermatocytes which in their turn produce the gamete-cells, it is observed that the male and female chromosomes make a last appearance in their full number, and then fuse in pairs, so as to reduce the number of chromosomes to half that previously present.

As Vejdovsky has pointed out, there can be no more striking evidence of the specific individuality of the chromosomes than their fusion or copulation in relation to the sexual act. Is there any other constant element or constituent of living organisms exhibiting to anything like the same degree the essentially vital characteristics of individuality manifested in specific behaviour? If there is, it remains to be discovered.

I come now to the question of the permanence and immortality, in the biological sense of the word, of the chromatinic particles, which may be summarily stated as follows: the chromatinic particles are the only

[2] E. B. Wilson, "The Cell," second edition, 1911, pp. 30, 31.

constituents of the cell which maintain persistently and uninterruptedly their existence throughout the whole life-cycle of living organisms universally.

I hope I shall not be misunderstood when I enunciate this apparently sweeping and breathless generalisation. I am perfectly aware that in the life-cycle of any given species of organism there may be many cell-constituents besides the chromatin-particles that are propagated continuously through the whole life-cycle; but cell-elements which appear as constant parts of the organisation of the cell throughout the life-cycle in one type of organism may be wanting altogether in other types. With the exception of the chromatin-particles there is no cell-constituent that can be claimed to persist throughout the life-cycles of organisms universally. It may be that this is only the result of our incomplete knowledge at the present time. I am prepared, however, to challenge anyone to name or to discover any cell-constituent, other than the chromatinic particles, which are present throughout the life-cycle, not merely of some particular organism, but of organisms universally.

To recapitulate my argument in the briefest form; the chromatinic constituents of the cell contrast with all the other constituents in at least three points: physiological predominance, especially in constructive metabolism; specific individualisation; and permanence in the sense of potential biological immortality. Any of these three points, taken by itself, is sufficient to confer a peculiar distinction, to say the least, on the chromatin-bodies; but taken in combination they appear to me to furnish overwhelming evidence for regarding the chromatin-elements as the primary and essential constituents of living organisms, and as representing that part of a living body of any kind which can be followed by the imagination, in the reverse direction of the propagative series, back to the very starting-point of the evolution of living beings.

In the attempt to form an idea as to what the earliest type of living being was like, in the first place, and as to how the earliest steps in its evolution and differentiation came about, in the second place, we have to exercise the constructive faculty of the imagination guided by such few data as we possess. It is not to be expected, therefore, that agreement can be hoped for in such speculations; it would indeed be very undesirable, in the interests of science, that there should be no conflict of opinion in theories which, by their very nature, are beyond any possibility of direct verification at the present time. The views put forward by any man do but represent the visions conjured up by his imagination, based upon the slender foundation of his personal knowledge, more or less limited, or intuition, more or less fallacious, of an infinite world of natural phenomena. Consequently such views may be expected to diverge as widely as do temperaments. If, therefore, I venture upon such speculations, I do so with a sense of personal responsibility and as one wishing to stimulate discussion rather than to lay down dogma.

To me, therefore, the train of argument that I have set forth with regard to the nature of the chromatinic constituents of living organisms appears to lead to the conclusion that the earliest living beings were minute, possibly ultramicroscopic particles which were of the nature of chromatin. How far the application of the term chromatin to the hypothetical primordial form of life is justified from the point of view of substance, that is to say in a biochemical sense, must be left uncertain. In using the term chromatin I must be understood to do so in a strictly biological sense, meaning thereby that these earliest living things were biological units or individuals which were the ancestors, in a continuous propagative series, of the chromatinic grains and particles known to us at the present day as universally-occurring constituents of living organisms. Such a conception postulates no fixity of chemical nature; on the contrary, it implies that as substance the primitive chromatin was highly inconstant, infinitely variable, and capable of specific differentiation in many divergent directions.

For these hypothetical primitive organisms we may use Mereschkowsky's term biococci. They must have been free-living organisms capable of building up their living bodies by synthesis of simple chemical compounds. We have as yet no evidence of the existence of biococci at the present time as free-living organisms; the nearest approach to any such type of living being seems to be furnished by the organisms known collectively as Chlamydozoa, which up to the present have been found to occur only as pathogenic parasites. In view, however, of the minuteness and invisibility of these organisms, it is clear that they could attract attention only by the effects they produce in their environments. Consequently the human mind is most likely to become aware in the first instance of those forms which are the cause of disturbance in the human body. If free-living forms of biococci exist, as is very possible and even probable, it is evident that very delicate and accurate methods of investigation would be required to detect their presence.

If it be permissible to draw conclusions with regard to the nature of the hypothetical biococci from the somewhat dubious, but concrete, data furnished by the Chlamydozoa, the following tentative statements may be postulated concerning them. They were (or are) minute organisms, each a speck or globule of a substance similar in its reactions to chromatin. Their substance could be described as homogeneous with greater approach to accuracy than in the case of any other living organism, but it is clear that no living body that is carrying on constructive and destructive metabolism could remain for a moment perfectly homogeneous or constant in chemical composition. Their bodies were not limited by a rigid envelope or capsule. Reproduction was effected by binary fission, the body dividing into two with a dumbbell-shaped figure. Their mode of life was vegetative—that is to say, they reacted upon their environmental medium by means of ferments secreted by their own body-substance. The earliest forms must have possessed the power of building up their protein-molecules from the simplest inorganic compounds; but different types of biococci, characterised each by specific reactions and idiosyncrasies, must have become differentiated very rapidly in the process of evolution and adaptation to divergent conditions of life.

Consideration of the existing types and forms of living organisms shows that from the primitive biococcal type the evolution of living things must have diverged in at least two principal directions. Two new types of organisms arose, one of which continued to specialise further in the vegetative mode of life, in all its innumerable variations, characteristic of the biococci, while the other type developed an entirely new habit of life—namely, a predatory existence. I will consider these two types separately.

(1) In the vegetative type the first step was that the body became surrounded by a rigid envelope. Thus came into existence the bacterial type of organism, the simplest form of which would be a Micrococcus, a minute globule of chromatin surrounded by a firm envelope. From this familiar type an infinity of forms arise by processes of divergent evolution and adaptation. I will not attempt, however, to follow up the evolution of the bacterial type further, or to discuss what other types of living organisms may be affiliated with it, as I have no claims to an expert knowledge of these organisms.

(2) In the evolution from the biococcus of the pre-

datory type of organism, the data at our disposal appear to me to indicate very clearly the nature of the changes that took place, as well as the final result of these changes, but leave us in the dark with regard to some of the actual details of the process. The chief event was the formation, round the biococci, of an enveloping matrix of protoplasm for which the term periplasm (Lankester) is most suitable. The periplasm was an extension of the living substance which was distinct in its constitution and properties from the original chromatinic substance of the biococcus. The newly formed matrix was probably from the first a semi-fluid substance of alveolar structure and possessed two important capabilities as the result of its physical structure; it could perform streaming movements of various kinds, more especially amœboid movement; and it was able to form vacuoles internally. The final result of these changes was a new type of organism which, compared with the original biococci, was of considerable size, and consisted of a droplet of alveolar, amœboid periplasm in which were imbedded a number of biococci. Whether this periplasm made its first appearance around single individual biococci, or whether it was from the first associated with the formation of zooglœa-like colonies of biococci, must be left an open question.

Thus arose in the beginning the brand of Cain, the prototype of the animal—that is to say, a class of organism which was no longer able to build up its substance from inorganic materials in the former peaceful manner, but which nourished itself by capturing, devouring, and digesting other living organisms. The streaming movements of the periplasm enabled it to flow round and engulph other creatures; the vacuole-formation in the periplasm enabled it to digest and absorb the substance of its prey by the help of ferments secreted by the biococci. By means of these ferments the ingested organisms were killed and utilised as food, their substance being first broken down into simpler chemical constituents and then built up again into the protein-substances composing the body of the captor.

A stage of evolution is now reached which I propose to call the pseudo-moneral or cytodal stage, since the place of these organisms in the general evolution of life corresponds very nearly to Haeckel's conception of the Monera as a stage in the evolution of organisms, though not at all to his notions with regard to their composition and structure. The bodies of these organisms did not consist of a homogeneous albuminous "plasson," but of a periplasm corresponding to the cytoplasm of the cell, containing a number of biococci or chromatin-grains. In the life-cycles of Protozoa, especially of Rhizopods, it is not at all infrequent to find developmental phases which reproduce exactly the picture of the pseudo-moneral stage of evolution, phases in which the nucleus or nuclei have disappeared, having broken up into a number of chromatin-grains or chromidia scattered through the cytoplasm.

The next stage in evolution was the organisation of the chromatin-grains (biococci) into a definite cell-nucleus. This is a process which can be observed actually taking place in many Protozoa in which "secondary" nuclei arise from chromidia. With the formation of the nucleus the cytode or pseudo-moneral stage has become a true cell of the simplest type, for which I propose the term *protocyte*. It is now the starting-point of an infinite series of further complications and elaborations in many directions. With all the diverse modifications of the cell the nucleus remains comparatively uniform. It may, indeed, vary infinitely in details of structure, but in principle it remains a concentration or aggregation of numerous grains of chromatin supported on some sort of framework over which the grains are scattered or clumped in various ways, supplemented usually by plastin or nucleolar substance either as a cementing ground-substance or as discrete grains, and the whole marked off sharply from the surrounding cytoplasm, with or without a definite limiting membrane. There is, however, one point in which the nucleus exhibits a progressive evolution of the most important kind. I refer to the gradual elaboration and perfection of the reproductive mechanism, the process whereby, when the cell reproduces itself by fission, the chromatin-elements are distributed between the two daughter-cells.

The chromatin-constituents of the cell are regarded, on the view maintained here, as a number of minute granules, each representing a primitive independent living individual or biococcus. To each such granule must be attributed the fundamental properties of living organisms in general; in the first place metabolism, expressed in continual molecular change, in assimilation and in growth, with consequent reproduction; in the second place specific individuality. As the result of the first of these properties the chromatin-granules, often perhaps ultra-microscopic, may be larger or smaller at different times, and they multiply by dividing each into two daughter-granules. As a result of the second property, chromatin-granules in one and the same cell may exhibit qualitative differences and may diverge widely from one another in their reactions and effects on the vital activities of the cell. The chromatin-granules may be either in the form of scattered chromidia or lodged in a definite nucleus. When in the former condition, I have proposed the term chromidiosome for the ultimate chromatinic individual unit; on the other hand, the term chromiole is commonly in use for the minute chromatin-grains of the nucleus.

In the phase of evolution that I have termed the pseudomoneral or cytodal phase, in which the organism was a droplet of periplasm containing scattered biococci or chromidiosomes, metabolism would result in an increase in the size of the cytode-body as a whole, accompanied by multiplication of the chromidiosomes. Individualisation of the cytodes would tend to the acquisition of a specific size—that is to say, to a limitation of the growth—with the result that when certain maximum dimensions were attained the whole cytode would divide into two or more smaller masses amongst which the chromidiosomes would be partitioned.

In the next stage of evolution, the protocyte with a definite nucleus, it is highly probable that at each division of the cell-body, whether into two or more parts, the primitive method of division of the nucleus was that which I have termed elsewhere "chromidial fragmentation"; that is to say, the nucleus broke up and became resolved into a clump of chromidiosomes, which separated into daughter-clumps from which the daughter-nuclei were reconstituted. Instances of nuclear divisions by chromidial fragmentation are of common occurrence among the Protozoa, and represent probably the most primitive and direct mode of nuclear division.

It is clear, however, that if the chromatin-grains are to be credited with specific individuality and qualitative differences amongst themselves, this method of nuclear division presents grave imperfections and disadvantages, since even the quantitative partition of the chromatin is inexact, while the qualitative partition is entirely fortuitous.

It is not surprising, therefore, to find that the process of nuclear division undergoes a progressive elaboration of mechanism which has the result of ensuring that the twin sister-granules of chromatin produced by division of a single granule shall be

distributed between the two daughter-cells, so that for every chromatin-grain obtained by one daughter-cell an exact counterpart is obtained by the other; in other words, of ensuring an exact qualitative, as well as quantitative, partition of the chromatin-particles. In its perfect form this type of nuclear division is known as karyokinesis or mitosis, and all stages in its progressive development are to be found in the Protozoa.

In the evolution of nuclear division by karyokinesis two distinct processes are being developed and perfected in a parallel manner, but more or less independently; first, the method of the partition and distribution of the chromatin-grains between the two daughter-nuclei; secondly, the mechanism whereby the actual division of the nucleus and the separation of the two daughter-nuclei are effected in the cell-division. I have dealt elsewhere with the evolution of the mechanism of karyokinesis as exemplified by the numerous and varied types of the process found amongst the Protozoa, and I need not discuss the matter further here, but the behaviour of the chromatin-grains may be dealt with briefly. The main feature in the process of the exact quantitative and qualitative distribution of the daughter-chromatin between the daughter-nuclei is the aggregation of the chromatin-grains or chromioles into definite, highly individualised structures known as chromosomes. In the most perfected forms of the process of chromosome-formation the chromioles become united into a linear series termed by Vejdovsky a chromoneme, which is supported upon a non-chromatinic basis or axis.

The actual division of the chromatin takes place by the longitudinal splitting of the chromoneme—in other words, by simultaneous division into two of each of the chromioles of which the thread is composed. In this way every chromiole which was contained in the original chromoneme is represented by a daughter-chromiole in each of the two daughter-chromonemes. It follows that the familiar process of the splitting of the chromosomes in karyokinesis is a mechanism which brings about in the most simple, sure and direct manner an exact quantitative and qualitative partition of the chromatin-grains between the two daughter-nuclei.

The chromatin-cycle of a cell in which the process of division by karyokinesis takes place in its most perfectly developed form, may, therefore, be conceived as follows. The nucleus in its resting state contains a definite number of companies or brigades of chromatinic units (chromioles), each brigade spread over a certain extent of the nuclear framework forming a karyomere. As a preparation to division each separate brigade of chromioles falls into line as the chromoneme, forming with its supporting substance the chromosome; there are formed, therefore, just so many chromosomes as there were karyomeres in the nucleus. In this disciplined and orderly array each chromiole undergoes its division into two daughter-chromioles, so that each file or chromoneme of chromioles splits into two files. At the reconstitution of the daughter-nuclei each daughter-chromosome gives rise to a karyomere again, the chromioles falling out of the ranks and disposing themselves in an apparently irregular manner on the newly built framework of the daughter-nucleus to constitute their own particular karyomere. Thus karyokinesis differs only from the most primitive method of division by chromidial fragmentation in that what was originally a haphazard method of distribution has become a disciplined and orderly manœuvre, performed with the precision of the parade-ground, but in a space far less than that of a nutshell.

In the nuclear division of Protozoa, without going into detail, it may be stated broadly that all stages are to be found of the gradual evolution of the tactical problem which constitutes karyokinesis.

I have dealt briefly with the problem of the evolution of karyokinesis because the process of nuclear division is, in my opinion, of enormous importance in the general evolution of living organisms. I have expressed elsewhere the opinion that the very existence of multicellular organisms composed of definite tissues is impossible until the process of karyokinesis has been established and perfected. For tissue-formation it is essential that all the cells which build up any given tissue should be similar, practically to the point of identity, in their qualities; and if it is the chromatin-elements of the cell which determine its qualities and behaviour, then the exact qualitative division of the chromatin, as effected in karyokinesis, is indispensable as a preliminary to the production of identically similar daughter-cells by division of a parent-cell. Hence it becomes intelligible why, amongst Metazoa, we find the occurrence of nuclear division by karyokinesis in its most perfect form to be the rule, and "direct" division of the nucleus to be the rare exception, while, on the other hand, in the Protista, and especially in the Protozoa, we find every possible stage in the gradual evolution of the exact partition of the chromatin in the process of nuclear division, from chromidial fragmentation or the most typical amitosis up to processes of karyokinesis as perfect as those of the Metazoa.

I have confined myself to the evolution of the cell as this organism is seen in its typical form in the bodies of the multicellular organisms, starting from the simplest conceivable type of living being, so far as present knowledge enables us to conceive it. But there is not the slightest reason to suppose that the evolution of the Protista took place only in the direction of the typical cell of the cytologist. Besides the main current leading up to the typical cell, there were certainly other currents tending in other directions and leading to types of structure very unlike the cells composing the bodies of multicellular organisms.

In this address I have set forth my conceptions of the nature of the simplest forms of life and of the course taken by the earliest stages of evolution, striving all through to treat the problem from a strictly objective point of view, and avoiding as far as possible the purely speculative and metaphysical questions which beset like pitfalls the path of those who attack the problem of life and vitalism. I have, therefore, refrained as far as possible from discussing such indefinable abstractions as "living substance" or "life," phrases to which no clear meaning can be attached.

How far my personal ideas may correspond to objective truth I could not, of course, pretend to judge. If I might be permitted to attempt an impartial criticism of my own scheme, I think it might be claimed that the various forms and types of organisms in my evolutionary series, namely, the simple cell or protocyte, the cytode or pseudomoneral stage, the micrococcus, even the biococcus, are founded on concrete evidence, and can be regarded as types actually existent in the present or past. On the other hand, the *rôle* assigned by me to each type in the pageant of evolution is naturally open to dispute. For example, I agree with those who derive the bacteria as primitive, truly non-cellular organisms, directly from the biococcus through an ancestral form, and not at all with those who would regard the bacteria as degenerate or highly specialised cells. But the crux of my scheme is the homology postulated between the biococcus and the chromatinic particle

—chromidiosome or chromiole—of true cells. In support of this view, of which I am not the originator, I have set forth the reasons which have convinced me that the extraordinary powers and activities exhibited by the chromatin in ordinary cells are such as can only be explained on the hypothesis that the ultimate chromatinic units are to be regarded as independent living beings, as much so as the cells composing the bodies of multicellular organisms; and, so far as I am concerned, I must leave the matter to the judgment of my fellow-biologists.

I may point out, in conclusion, that general discussions of this kind may be useful in other ways than as attempts to discover truth or as a striving towards a verity which is indefinable and perhaps unattainable. Even if my scheme of evolution be but a midsummer night's fantasy, I claim for it that it co-ordinates a number of isolated and scattered phenomena into an orderly and, I think, intelligible sequence, and exhibits them in a relationship which at least enables the mind to obtain a perspective and comprehensive view of them. Rival theories will be more, or less, useful than mine, according as they succeed in correlating more, or fewer, of the accumulated data of experience. If in this address I succeed in arousing interest and reflection, and in stimulating inquiry and controversy, it will have fulfilled its purpose.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—A portrait of Prof. Lapworth (by Mr. B. Munns) has been presented to the University by Mr. W. Waters Butler.

Dr. Elgood Turner has been appointed demonstrator in anatomy for women students in succession to Dr. Violet Coghill, who has resigned.

Dr. Mary Clarke has been appointed lecturer in hygiene to the students of the Training College for Women.

Mr. B. Lloyd has been appointed demonstrator in anatomy for the session.

GLASGOW.—Prof. John Ferguson has resigned the Regius chair of chemistry, to which he was appointed in 1874. He had previously for nine and a half years been a junior teacher in the department. He has therefore been a member of the staff for more than fifty years. During his tenure of office the chemical laboratories of the University have been greatly enlarged, and separate departments of organic chemistry, metallurgical chemistry, and physical chemistry have been instituted under the charge of special lecturers. Among Prof. Ferguson's former pupils are many distinguished chemists, including Prof. Millar Thomson, Sir William Ramsay, Sir J. J. Dobbie, Carrick Anderson, Profs. Henderson, Boyd, Long, and Parker, and Dr. A. W. Stewart.

LEEDS.—The Vice-Chancellor has received the following message from the King:—"His Majesty feels that the assistance of the universities is a great asset to the cause for which we are fighting, as science plays such a prominent part in modern warfare."

LONDON.—A course in dynamical meteorology with practical work will be given at the Meteorological Office, South Kensington, on Fridays, at 3 p.m., during the second term by Sir Napier Shaw, director of the Meteorological Office and University reader in meteorology. The fortnightly meetings at the Meteorological Office for discussion of important contributions to current meteorology in colonial or foreign journals will be resumed at 5 p.m. on Monday, October 25, and will be continued on alternate Mondays until March 27, 1916, with the exception of December 20th and January 3. Students wishing to attend should communicate with the reader at the Meteorological Office. The lectures are addressed to advanced students of the University and to others interested in the subject. Admission free, by ticket, to be obtained on application at the Meteorological Office.

A COPY of the September issue of the *Reading University College Review* has been received. It contains a revised list of the names of present members of the staff, past and present students, and present servants of the college who are serving with his Majesty's Forces, or in the French Army. The college may well be proud of its roll of honour. Mr. W. E. G. Atkinson, who was formerly a lecturer of the Department of Agriculture, has been killed in action in the Dardanelles, and Mr. T. G. Malpas, demonstrator in the physics laboratory, has been wounded. The review also contains a list of recent original contributions to science by members of the staff.

THE various courses of instruction to be given at the North of Scotland College of Agriculture during the present session are set out in detail in the current calendar of the college. The courses are designed to prepare students for the degree of B.Sc. in agriculture in the University of Aberdeen, the university diploma in agriculture, the national diplomas in agriculture and dairying, the degree of B.Sc. in forestry, and the certificate in forestry granted by the Highland and Agricultural Society of Scotland. All courses are open to women as well as to men. With the aid of a grant from the Development Commission, a research department has been instituted. In accordance with the conditions under which the grant is received from the Commission, this department is managed by a joint committee representing the governors and the University Court. We notice the governors have acquired a college farm. Experiments and demonstrations will be carried out. Experimental plots, an experimental and demonstration garden, and a horticultural department, are in course of construction. It is also intended to carry on feeding and other experiments upon stock. The farm is conveniently situated about five miles from Aberdeen. It is proposed to institute a school of rural domestic economy for girls. There is a large mansion house on the college farm estate which will be equipped as a residence for the girls attending the school, and in which classes will be carried on.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 4.—M. Ed. Perrier in the chair.—J. **Boussinesq**: The correct calculation of the influence of climatic inequality on the velocity of increase of terrestrial temperatures with depth from the surface.—H. **Douvillé**: The orbitoids of the peninsula of California. A study of material arising from the geological explorations of Arnold Heim. Some specimens belong to the genus Orthophragmina, and it is the first time these have been discovered in this region. Some rare Foraminifera include specimens of *Amphistegina Niasi*.—E. E. **Barnard**: Some supposed movements in stars near the cluster Messier 11 = N.G.C. 6705. The observation of J. Comas Solá on movements of stars in the neighbourhood of this cluster do not appear to be well founded. They were based on the stereoscopic examination of photographs taken at an interval of three years. The author has examined photographs of the same

region separated by an interval of twenty-two years, making use of a Zeiss stereo-comparator, but no movement of the stars in question can be observed.—J. Comas **Solá**: The approximate positions of a small planet, apparently new.—C. **Camichel**: Hammering in water pipes entirely free from air. Experimental determinations of the velocity of wave transmission in an 80 mm. iron pipe, 154 metres long, and of the pressures produced by sudden closing of a tap in the main.—Alb. **Colson**: The heat disengaged by a solid body passing to the state of saturated or dilute solutions. Details of experimental studies by a new method on the heats of solution of common salt.—B. **Bogitch**: The reciprocal solubility of copper and lead. Copper and lead form a double layer when the amount of copper exceeds 34·5 per cent., and is below 87 per cent. This double layer can only exist between the temperature of solidification of the upper layer (940° C.) and 975° C.—Arnold **Heim**: The geology of the southern part of lower California.—MM. **Debierne** and **Regaud**: The use of the condensed radium emanation in closed tubes in the place of radium compounds, and the estimation (in millicuries of emanation destroyed) of the energy used up in radio-active applications in general. An account of the advantages, from the points of view of economy and ease of application, of condensed radium emanation for biological purposes.

NEW SOUTH WALES.

Linnean Society, August 25.—Mr. A. G. Hamilton, president, in the chair.—R. J. **Tillyard**: The physiology of the rectal gills in the larvæ of anisopterid dragonflies. The minute structure of the rectal gill was studied to find evidence for a solution of the difficult problem of the physiology of respiration in these organs. Seven separate elements are recognisable in the gills. The argument excludes four of these, leaving only three, viz., the cuticle, the epithelial syncytium of the gill, and its tracheal capillary loops, as the agents of respiration. These are suited for respiration by diffusion of gas from the rectal water-supply through the cuticle and syncytium into the capillaries. The old objection to this diffusion theory, viz., that it can be understood easily when once started, but that there is no explanation of how it could begin in the newly-hatched nymph, is disposed of by observations on the process of hatching, which prove that the tracheal gas is not derived in the first instance from the rectal water-supply, but from some unknown source in the anterior end of the larval body.—T. G. **Sloane**: Studies in Australian entomology. No. XVII.—New genera and species of Carabidæ. This instalment treats of the tribes Pamborini, Migadopini, Broscini, Cuneipectini, Nomiini, Pterostichini, Platynini, Oodini, Harpalini, and Lebiini. Four genera and thirty-two species are described as new; among the most noteworthy being—a new species of Pamborus, a new genus of the Antarctic tribe Migadopini, an additional species of the genus Cuneipectus (the type of a tribe confined to western Australia), and a species of Phorticosomus, which has the submentum bearing two horn-like processes, a character known only in the allied genus Dioctes from the Steppes east of the Caspian Sea.—O. B. **Lower**: Descriptions of new Australian Lepidoptera. Twenty-one species, referable to the Geometridæ, Monocteniadæ, Selidosemidæ, Limacodidæ, Ocneriadæ, Zeuzeridæ, Pyraustidæ, Œcophoridæ, and Xyloryctidæ, are described as new; with one exception, all are from Pinnaroo, South Australia, or from Broken Hill, N.S.W., or from both localities.

CAPE TOWN.

Royal Society of South Africa, August 18.—Dr. L. Péringuey, president, in the chair.—J. W. **Bews**: The growth forms of Natal plants. The author gives a detailed description of his work on the growth forms of Natal plants. The investigation of the growth forms of plants in relation to their environment is being recognised as a very important, if not the most important, branch of plant ecology. The study of the various plant communities and their determination by the environmental factors presents a more general aspect of the subject, and has hitherto perhaps on the whole received more attention from plant ecologists, though, of course, it includes a certain amount of the study of the separate growth forms. It is, however, in the more detailed study of the "epharmony" of the species of plants that a deeper insight is gained into the cause and effect relationship existing between the environment and plant life.—I. B. Pole **Evans**: The South African rust fungi. I. The species of Puccinia on Compositæ. Descriptions and accompanying notes are given of the species of Puccinia based mainly upon material which the author and his colleagues have collected during the past ten years in South Africa, and which is now represented in the Mycological Herbarium of the Union of South Africa at Pretoria. The material has been collected primarily with the object of elucidating the life-histories of the various rusts which are so destructive to many of our economic crops, and it is hoped that the descriptions of these parasites, of which this is the first instalment, may promote a more widespread interest in this group of plants, and may be the means of adding considerably to our present very imperfect knowledge of these fungi.—J. Steph. v. d. **Lingen**: Heating and cooling apparatus for Röntgen crystallographic work. The apparatus described has been devised by the author in order to facilitate the work of those who wish to carry on research on the determination of the energy of an atom at zero temperature and at very high temperatures. The energy of atoms and its relation to temperature is one of the many problems of modern physics. Since the publication of de Bye's extension of Laue's theory of Röntgen interference, several experiments have been performed with a view to determine, first, the validity of de Bye's theory, and, secondly, the variation of atomic energy due to "heat motion."

SCIENCE IN NATIONAL AFFAIRS.

WE printed last week a valuable address by Prof. J. A. Fleming on "Science in the War and after the War." Though the address was an introductory lecture at University College, London, and was open to the public without fee or ticket, only the briefest mention of it appeared in the periodical Press, and the points of national importance dealt with in it were unrecorded, except in our columns, in which it was our privilege to publish the address almost in full. We understand, of course, that the demands made upon the space available in the daily papers are many and insistent, yet we should have supposed that during the progress of a war in which victory will depend as much upon science and machinery as upon men, a summary of some of the points made by a leading authority upon applied science would be of greater public interest and importance than much of the unsubstantial chatter with which we are supplied daily.

In the course of his address, Prof. Fleming himself supplied a reason for the neglect of scientific aspects of national affairs, in comparison with the attention given to the superficial views of politicians and other publicists. While success in science is measured solely by discovery of facts or relationships, in politics and public life generally it is secured by fluent speech and facile pen. In scientific work attention must be concentrated upon material fact, but the politician and the writer attach greater importance to persuasive words and phrases, and by their oratory or literary style are able to exert an influence upon public affairs altogether out of proportion to their position as determined by true standards of national value. Power, as regards government of the affairs of the nation, does not come from knowledge, but from dialectics: it is the lawyer who rules, with mind obsessed by the virtues of precedent and expediency, and to him men of science and inventors are but hewers of wood and drawers of water.

Under a democratic constitution it is perhaps too much to expect that Parliament will pay much attention to scientific men or methods; yet, as was shown in the debate upon the scheme for the institution of an advisory council of scientific and industrial research last May, the members of the House of Commons are ready to support plans for bringing science in closer connection with industry. The monies provided by Parliament for this purpose are to be under the control of a committee of the Privy Council, which will be advised by a council constituted of scientific and industrial experts. The scheme was conceived rightly enough, but when it passed into the hands of officials of the Board of Education much of its early promise was lost. Most people would regard it as essential that the executive officers of a council concerned with the promotion of industrial research should know what is done in this direction in other countries, and have sufficient knowledge of science and industry to formulate profitable schemes of work. The success of such a body depends largely upon the initiative of the secretary; and in an active and effective council we should expect him to be selected because of close acquaintance with problems of industrial development along scientific lines. But what is the position in this case? The scheme is issued by the President of the Board of Education, Mr. Arthur Henderson, a Labour member, who owes his post entirely to political exigencies, the secretary to the committee of the Privy Council is the Secretary of the Board, Sir Amherst Selby-Bigge, whose amiability is above reproach, but who knows no more of practical science and technology than a schoolboy, and the secretary of the Advisory Council is Dr. H. F. Heath, whose interests are similarly in other fields than those of science.

The belief that the expert—whether scientific or industrial—has to be controlled or guided by permanent officials having no special knowledge of the particular subject in hand is typical of our executive system. While such a state of things exists, most of the advantages of enlisting men of science for national services must remain unfulfilled. The various scientific committees which have been appointed recently have, we believe, been able to give valuable aid in connection with problems submitted to them, but they would be far more effective if the chiefs of the departments with which they are associated possessed a practical knowledge of scientific work and methods. Without such experience the executive is at the mercy of every assertive paradoxer and cannot discriminate between impracticable devices and the judgment of science upon them. While, therefore, the country has at its disposal the work—either voluntary or nearly so—of experts in all branches of applied science, it cannot use these services to the best advantage unless the departments concerned with them have scientific men among the permanent officials; and that is not the case at present.

I

The unbusinesslike methods of Government departments have received severe criticism lately, but nothing has been said about the unscientific method of appointing committees of experts without well-qualified officers to direct or co-ordinate their work. The reason is that, with scarcely an exception, no daily paper has anyone on its staff possessing the most elementary knowledge of the meaning of scientific research. Our guides and counsellors, both on the political platform and in the periodical Press, can scarcely be expected to interest themselves greatly in subjects beyond their mental horizon, so when scientific matters are involved they confine themselves to a few platitudes, or say nothing at all. They are unable to distinguish a quack from a leading authority in science, and prefer to exercise their imaginations upon sensational announcements, rather than discuss the possibilities of sober scientific discovery. In all that relates to the interests of science—and that means in the end the interests of the nation—the men who influence public opinion and control the public Services are mostly unenlightened and therefore unsympathetic.

The tacit assumption that public committees or departments concerned with scientific problems must have at their head officers of the Army, Navy, or Civil Service is responsible for delay in taking advantage of available expert knowledge and for the neglect to make effective use of science in national affairs, whether in times of war or peace. Just as a member of the Government may serve in turn as president of the Board of Education, Board of Agriculture, Board of Trade, or any other department, without possessing any special qualifications to comprehend the work of either, so a public official may be placed in a position to dominate activities of which he cannot understand the significance. Some day we hope that this mad system will be swept away, and that the men who exert control in all Government offices will be those whose training or experience make them most capable of doing so effectively.

Neither the political nor the official mind in this country yet realises the power which science can give to the modern State; because classical and literary studies still form the chief high-road to preferment in Parliament or in public offices. From the elementary school to the university truly scientific work occupies but a very secondary position in comparison with the humanities. In these days the material advancement of a nation must depend upon the developments of science and technology; and care should be taken, therefore, to create interest in these subjects and foster attention to them throughout the curriculum or course of school and college. Many people no doubt believe that this is being done, but it is far from being the case, and the promise of a generation ago is likely to be unfulfilled while the power over expenditure upon practical education remains in the hands of men who have no sympathy with it. Men who are distinguished for their scientific work, or have had a practical training in science, are on the staff of the Board of Education, but they are all subordinate to officers whose interests are in other fields; and scientific education suffers accordingly. Thus it comes about that Mr. C. A. Buckmaster, late Assistant Secretary under the Board of Education, could say in an address to the Educational Science Section of the British Association last year:—

"There can be no doubt that there is less real systematic science teaching in our elementary schools than was the case twenty years ago, and that the proportion of the total expenditure on elementary education which can be looked upon as spent in promoting science instruction is decidedly less, not only in proportion, but in amount. . . . It is not too much to say that the weight of official recognition has passed from the scientific to the literary side of the secondary school, and that the time and energy devoted to instruction and practical work in science have shown a remarkable decrease."

Was there ever a more severe indictment of the literary official's inability to prepare the citizens of a modern State for the struggles before them than is contained in these conclusions as to the position of science in our schools? A quarter of a century ago scientific studies were gaining increased attention in the curriculum, and there was reason to hope that one generation would succeed another with greater ability to compete with other progressive peoples, and with increased distrust of political obscurantists and the pretensions of literary culture. We have not gained this power because the control of our educational system from bottom to top has been, and is, in the hands of men without knowledge of modern needs or of the essential difference between the study of words and of things. To the deadening influence of these official representatives of the humanities must be ascribed the deplorable fact that public interest in scientific matters or appreciation of the worth of scientific research is less intelligent, and relatively less extensive, than it was fifty years ago.

To the literary mind, a man of science is a

callous necromancer who has cut himself off from communion with his fellows, and has thereby lost the throbbing and compassionate heart of a full life; he is a Faust who has not yet made a bargain with Mephistopheles, and is therefore without human interest. Scientific and humanistic studies are, indeed, supposed to be antipathetic and to represent opposing qualities; so that it has become common to associate science with all that is cold and mechanistic in our being, and to believe that the development of the more spiritual parts of man's nature belongs essentially to other departments of intellectual activity.

"When scientific work is undertaken solely with the object of commercial gain, its correlative is selfishness; when it is confined to the path of narrow specialisation, it leads to arrogance; and when its purpose is materialistic domination, without regard to the nobler deeds of humanity, it is a social danger and may become an excuse for learned barbarity. But research is rarely inspired by these motives, nor does devotion to it necessarily inhibit interest in other notes with which a well-balanced mind should be in resonance. Direct contact with Nature and inquiry into her laws do, however, produce a habit of mind which cannot be acquired in literary fields, and they are associated with a wide outlook on life more often than is popularly supposed. Science is not only able to increase the comforts of life and add to material welfare, but also to inspire the highest ethical thought and action; and a prominent place should be given to it in all stages of educational work as much on account of its ennobling influence as because it is a creator of riches.

Success in science means the birth of new knowledge. Patient observation and productive thinking are what the world needs for progress, and what true scientific study demands. There are now so many opportunities of obtaining ready-made opinions that the habits of independent thought, caution in accepting assertion, and critical inquiry into evidence, are suffering atrophy by disuse. *Vox populi, vox Dei*, may be a sound democratic principle for political platforms, but it stands for nothing in science. The men who have advanced the human race throughout the ages are they who have stood for individuality as against the voice of the crowd. We need such leaders now, men who will guide the people instead of waiting for a mandate from them before embarking upon any enterprise; and we need, above all, that the chief officials of departments of State should have had a training in scientific methods before being entrusted with the control of national affairs. While indifference to these things is the distinguishing characteristic of our statesmen and administrative officers, it is useless to expect that the nation's business will be conducted efficiently or its scientific forces be organised on the large scale which modern conditions demand.

ANALYTICAL CONTROL OF MODERN DYES.

The Analysis of Dyestuffs and their Identification in Dyed and Coloured Materials, Lake Pigments, Foodstuffs, etc. By Prof. A. G. Green. Pp. ix + 144. (London: C. Griffin and Co., Ltd., 1915.) Price 8*s*. 6*d*. net.

MODERN developments in the manufacture of synthetic colouring matters have now rendered it possible for the dyer to obtain any desired shade of colour in many different ways, but the suitability of the colour to the conditions under which the dyed material is to be employed depends entirely on the blend of dyes selected. It is evident that some analytical control is desirable in order that the most favourable result can be guaranteed.

Largely owing to the labours, extending over many years, of the author and his collaborators, a method has now been devised which is sufficiently comprehensive and elastic to cope not only with all the known dyes, but also with mixtures of these substances.

The three introductory chapters of this work treat of the chemistry of colouring matters and of the classification of these materials according to their chemical and tinctorial properties. In regard to theories of the colour of organic dyes, Prof. Green seems still to be a faithful adherent of the "quinonoid" hypothesis, in spite of the fact that he has himself discovered at least one dyestuff, namely, primuline (p. 21), to which he has not ascribed a "quinonoid" chemical constitution. It should, however, be added that the practical scheme of analysis presented in this manual is based on the tinctorial properties of the dyes, and not on hypothetical views in regard to their chemical structure. An interesting table serves as the summary of these introductory chapters, in which the chief series of colouring matters are doubly classified in accordance with their chemical nature and their dyeing properties. This tabulation indicates in a striking manner the lines along which future research may lead to many still missing groups of dyes.

The analysis of the dyes in bulk leads to a division into four main classes, in which solubility in water, affinity for unmordanted cotton, and precipitation by tannin form the distinctive

properties. Further subdivision is effected by successive experiments on the reduction of the dyes and the oxidisability of their reduction products. Owing to recent intense activity in the manufacture of synthetic dyes, each subdivision nowadays contains apparently many members, but, on the other hand, many of the names under which dyes appear are only synonyms employed by different firms.

Although it is sometimes practically impossible to identify the specific dyes on any fabric, yet the author's scheme of analysis enables the analyst to refer these substances to their appropriate classes, after which complete identification may be achieved by comparative dye-tests with standard dyes of known constitution.

After a reference to the detection of artificial dyestuffs in articles of food, the scheme for identifying colouring matters on animal fibres is elaborated. The dyed fabric is subjected to "stripping tests," and also to the action of a reducing agent—in this instance, sodium formaldehyde-sulphoxylate (Rongalite). Separate tests are described for indigoid dyes and for mordants, and a few principles are laid down for the examination of woollen fabrics dyed with mixtures of dyes. In such cases, fractional reduction and "stripping" tests are useful, together with fractional separation by means of solvents.

The problem presented by dyed vegetable fibres is much more complicated than that arising from dyed wool. Many basic dyes, which, when applied to wool, are readily reduced by sodium hydrosulphite, are scarcely attacked by this reagent when they are fixed on tannin-mordanted cotton. Accordingly, the tannin mordant must first be removed by boiling the fabric with caustic soda solution saturated with sodium chloride, the latter compound being added to avoid stripping off the dye.

Certain azo-colours, especially the insoluble "ingrain" azo-derivatives formed on the fibre, offer considerable resistance to the reducing action of ordinary hydrosulphite, and are decolorised very slowly and imperfectly. To overcome this difficulty the reducing agent is rendered more active by the addition of a very small quantity of reducible compound or colouring matter. The most convenient catalyst or sensitiser for this purpose is anthraquinone, a small quantity of which is added to the sodium formaldehyde-sulphoxylate solution.

Indigo is still the premier blue dye, and on account of its high price and valuable tinctorial properties, the estimation of pure indigotin either in bulk or on the fibre is a matter of considerable commercial importance. Special attention may be directed to the method for estimating quantitatively the indigotin on animal fibres worked out by the author in collaboration with Gardner, Lloyd, and Frank, since this process affords an accurate means of detecting the great abuses obtaining in the prevalent practice of "topping" or "bottoming" indigo-dyed materials with other inferior colouring matters.

The identification of organic colouring matters, when carried out in the systematic manner advocated by the author, becomes an important branch of analytical chemistry, so that this handbook may be recommended not only to the makers and users of dyes, but also to all students of organic chemistry. The educational value of the treatise is well exemplified in the chapter on the determination of the constitution of azo-dyes, for the methods adopted would go far towards enabling the analyst to identify any one of the very large number of azo-colouring matters at present on the market.

An index of the principal colouring matters shows the position of these dyes in the analytical separations, which are arranged in twenty-six tables.

The present condition of military warfare existing between the principal industrial nations will, in all probability, be succeeded by a period of strenuous industrial competition between the belligerents. During this period the discoverers of new dyes will, for obvious reasons, no longer, as hitherto, endeavour to protect their discoveries by patents, but will rely rather on keeping secret the methods of manufacture and the chemical nature of the products. At this stage the analytical methods systematised by the author will acquire additional importance in their application to the investigation of new dyes of undisclosed constitution.

G. T. M.

RUDIMENTARY SCIENCE FOR COAL-MINERS.

An Introduction to Mining Science. A Theoretical and Practical Text-book for Mining Students. By J. B. Coppock and G. A. Lodge. Pp. x+230. (London: Longmans, Green and Co., 1915.) Price 2s. net.

THE object of this little book is to put before the young coal-miner a certain number of facts in elementary science, mainly chemistry and physics, in such a way as to impress them upon him more readily than can be done through the medium of ordinary text-books upon these sciences. Such subjects as combustion, flame, explosion, the atmosphere, mine gases, coal, etc., are treated, each in a short chapter, which commences with a few ele-

mentary scientific facts, generally illustrated by reference to phenomena which may fairly be expected to have come under the notice of an average youth, and by a few simple experiments, which the student is intended to repeat; the second part of each chapter indicates the application of the scientific facts thus inculcated to some portion of the miner's experience in the pit. Like all books that set out to teach only such portions of a science as find direct application in any particular branch of technology, this work deliberately sacrifices the educational value of science in order to arrive more rapidly and more easily at the results derived from the acquisition of scientific facts. It is undoubtedly a very good thing that a coal-miner should be thoroughly familiar with the fact that a combustible material intimately mixed with air forms an explosive mixture, but the acquisition of any number of such fragments of knowledge, however valuable in themselves, does not provide the mental training that is obtained by the systematic study of any branch of science. Such a book as the one under discussion should not therefore be regarded as an adequate substitute for scientific education, but at best as an introduction and an incentive to further and more regular study of the sciences involved. It is a book that may fairly be recommended to the higher classes of an elementary school in a coal-mining district, with the hope that it may give the lads a desire to pursue their scientific studies further in evening continuation schools, where they would take a regular course of easy chemistry or physics, or both.

The work upon the whole is well done; the main pitfalls in such a book lie in the direction of slipshod statements on the one hand and over-elaboration on the other. As an example of the former we may quote the statement on page 118 that hydrogen "is a colourless gas, violently explosive," and of the latter the attempt to teach the molecular structure of gases on page 2. The authors have, however, generally succeeded in steering their course fairly between either extreme, and the result is a book which should, as already said, be quite useful to beginners, and will leave them very little indeed to unlearn when they begin to advance further in their scientific studies.

MATHEMATICAL SCHOOL-BOOKS.

(1) *Arithmetic. Parts I., II., and III., complete with Answers.* By C. Godfrey and E. A. Price. Pp. xiii + 467. (Cambridge: At the University Press, 1915.) Price 4s.; without answers, 3s. 6d.

(2) *Pendlebury's New Concrete Arithmetic. Sixth Year.* By C. Pendlebury and H. Leather. Pp. 80. (London: G. Bell and Sons, Ltd.) Price 6d.

(3) *Plane Trigonometry.* By H. Leslie Reed. Pp. xiii + 290 + xvi. (London: G. Bell and Sons, Ltd., 1915.) Price 3s. 6d.

(4) *Statics. Part II.* By F. C. Fawdry. Pp. 159–305 + viii. (London: G. Bell and Sons, Ltd., 1915.) Price 2s.

(5) *Numerical Examples in Physics.* By H. S. Jones. Pp. xii + 332. (London: G. Bell and Sons, Ltd., 1915.) Price 3s. 6d.

(6) *Exercises in Laboratory Mathematics.* By A. W. Lucy. Pp. 245. (Oxford: At the Clarendon Press, 1915.) Price 3s. 6d.

THE ideal text-book of arithmetic still remains to be written, and the time has not yet come when the ideal book would be a financial success. It will equip the boy or girl with the knowledge of the subject necessary for his other studies and his after-life. It will drop some branches which have in the past had usefulness but are now useless, and it will refrain from dealing with problems the subject-matter of which is outside a boy's experience and unintelligible to him, even if the calculation involved is simple once the subject-matter is understood. The ideal book with our present imperial system of weights and measures will easily be comprised within a hundred pages, and when the imperial system is dropped and the metric system becomes general the length will be further reduced.

The discussion of prime factors, greatest common measure, and least common multiple leads up to the extraction of square and cube roots, the reduction of fractions to their lowest terms, the addition of fractions, and the simplification of complicated expressions. Now the final convenient form for any fraction (except the very simplest) is the decimal form, and instead of reducing a fraction to its lowest terms we turn it straight away into a decimal. For the addition of fractions, in place of the vulgar method with all the labour of common denominators, we convert each fraction to a decimal (to as many significant figures as we need), and then add. Complicated expressions rarely turn up in natural problems; they are in the main the invention of examiners and text-book writers. Very little time, therefore, need be spent upon prime factors, greatest common measure, and least common multiple, and these will occupy little space in the ideal text-book.

"Stocks and shares" should also be omitted. The arithmetic is of the simplest. The trouble is partly in the difficulty of the subject-matter, partly in the unfamiliarity of the subject-matter, and partly in the unsuitable nomenclature, so poor

in distinctions between face value and selling value, and so full of terms among which master and boys are equally at sea.

Some schools neglect arithmetic sadly, while others give it far more time than its real worth deserves. The latter group are responsible for the bulk of the present-day text-book, in their demand for endless examples. In these schools the correction of the overcrowded time-table will in time reduce the number of periods allotted to arithmetic, and the text-book will be reduced to a fraction of its present size.

(1) Meantime we have to make the best of present conditions, and Messrs. Godfrey and Price have produced a most usable arithmetic. While compelled to run to above four hundred pages and include all the customary items and tricks (except recurring decimals, for which omission we are thankful), they show in the preface how they would prefer to use the boy's time. Their explanations of difficult points are accurate, concise, and clear; see, for instance, their discussion of fractions. They have regard also to the recommendations of various open-minded and wise bodies, such as the Headmasters' Conference, the British Association Committee on type in school-books, and the Mathematical Association Committee. The book is to be highly recommended; it provides work for the most lavish use of time, and the wise master who limits the time for arithmetic has a wide choice in his selection of work.

There is much gain in clearness of type by the use of the solidus, for instance, in printing "19/20" to stand for nineteen-twentieths, but it is a pity to use the symbol to denote shillings in the same book.

In elementary schools, also, arithmetic is in a bad way. Not that the boys don't do it well. They do it only too well, and can tackle the most abstruse questions which, if done at all, ought to be done by algebra. Further, they can (or are expected to) tackle questions which are unintelligible to the plain, well-educated man; in these questions conventional meanings, used only in schools, are put upon phrases which are otherwise meaningless. That abomination, the recurring decimal, is firmly entrenched in the elementary school, and children are told to commit to memory the expressions as recurring decimals of all proper fractions with denominator 7. After such enormities it seems quite natural to find the children required to add together 6 days and 23 seconds, or 16 kilometres and 2 millimetres.

(2) In the "New Concrete Arithmetic" the authors are doing the best that is possible in the circumstances. The whole gamut of absurdities must be included if the book is to sell, and so long as the present excessive allowance of time is given to the subject it is difficult to provide a sufficient number of varied questions without degenerating at times into unsuitabilities. The idea of first presenting every rule in concrete form is good; it might be carried further, and require every question to be such as naturally arises in human life. It would be still better to require every question to be such as arises in the pupil's own environment, so that there might be a rural arithmetic for the country school and various kinds of industrial arithmetics for town schools. Before such arithmetics are possible, however, the time allotted to the subject must be severely cut down. For to restrict the book to natural human problems and such bookwork as is necessary for their treatment, means the excision of many whole sections.

Let us repeat that we impute no blame to Mr. Pendlebury and Mr. Leather, who do the best that circumstances allow. In everything the book is as good as others of the kind, and in beginning from the concrete it is miles ahead of the bulk of them.

(3) In trigonometry also the mathematical master—or the headmaster or somebody—sets apart too much time for the subject. The time has to be filled in, but how can it be done without "Identities"? Identities being fashionable must be included in any book that is to be a success on the market. Mr. Reed is not to blame; he cannot help himself. First let the time allowed in the school for mathematics as a whole, or for trigonometry, be cut down, and Mr. Reed will write you a good book. He will discard identities, and identities being gone he will discover that secants and cosecants and tangents have no use except for the specialist and for the making of identities, and he will drop them.

In the meantime Mr. Reed does what is possible. He begins the solution of triangles by formulas most of which result immediately from geometrical properties. In the only case that presents any difficulty, that in which three sides are given, the method of solution is due to Prof. Bryan; expressions are found for the sum and difference of the two portions into which a side is divided by a perpendicular from the opposite vertex.

The variety of the questions which are taken from human life deserves high praise; it is only by long-continued effort that they could have been collected.

We regret, however, to find results left in surd form, as on pages 140 and 141, with the remark that they "may be worked decimally." We should have expected Mr. Reed to set a good example by "working them decimally" himself.

(4) This book—"Statics," by F. C. Fawdry—can be confidently recommended. The problems dealt with come from house-building, bridge-building, engineering, and other human activities. We no longer meet the ridiculous and perfectly smooth elephant who balances himself on a perfectly rough cricket ball. The good and simple methods of the engineer, hitherto excluded from the school-book, now come to their own, and the book discusses within the limits of 150 pages the link polygon, Bow's notation, the bending of beams, brake horse-power, and three dimensional problems, and discusses them well. The only fault we have to find is that the author cannot spell *parallelepiped*.

(5) We scarcely know what to say about this book of Examples in Physics. It is most virtuous in drawing all its exercises from human life, or at least from the laboratory. There are none of the wicked old questions that prevailed when an irresistible projectile used to impinge on an immovable obstacle. But, after all, what shall it profit a man to work through all these virtuous questions and be unable to tell a galvanometer from a lens? The examples should surely go with work in the laboratory; and if a man works in a laboratory he finds his own data there, and does not want to have them supplied in a book.

(6) This is a good, honest, plodding book, providing all the intellectual apparatus we are entitled to get under the name of "Laboratory Mathematics," but scarcely with the clearness of statement and crispness of effect that the ideal book would have. The attempt to consider weight and mass separately is somewhat ambitious for a book of this range; until quite an advanced stage it is better for the student to be content with one of them. Again the term "specific density" is unfortunately like "density" to use for so different a meaning as the author gives it, and the distinction between "specific density" and "specific gravity" is too subtle for the ordinary mortal.

D. B. M.

OUR BOOKSHELF.

Amoebiasis and the Dysenteries. By Prof. L. P. Phillips. Pp. xi+147. (London: H. K. Lewis, 1915.) Price 6*s*. 6*d*. net.

DYSENTERY is a clinical term used to denote disease conditions running more or less the same course, but dependent upon various ætiological agents. The subject is one of great and growing importance, and the advance in our knowledge of it has of late been considerable, but the literature is much scattered. In the volume under review Dr. Phillips has summarised the whole subject, and has compiled a book which should be of considerable value and assistance to all those who have to deal with this disease.

The various forms of dysentery are discussed from the point of view of their causation, viz., amœbiasis or amœbic infection, ciliate and flagellate dysentery, bilharzial dysentery, and bacillary dysentery. Amœbic dysentery is caused by infection with an amœbiform protozoon, now known as the *Entamoeba histolytica*. A full description is given of this parasite and of its differentiation from other forms of amœbæ. There is so far as at present known only one organism causing amœbic dysentery, and this cannot be artificially cultivated, though several saprophytic forms seem to have been grown in the laboratory.

There is undoubtedly a form of dysentery due to infection by a ciliate organism, *Balantidium coli*, and the disease is probably not so rare as the published cases seem to show. Several flagellate protozoa are also under suspicion as causal agents in dysentery or dysenteric diarrhœa.

A very chronic form of dysentery is associated with bilharzial infection of the large intestine, particularly in Egypt; the parasite in this case is a worm. Lastly, there is the bacillary form of the disease, due to a bacillus of world-wide distribution, and apt to occur in epidemics, thus differing from amœbic dysentery.

Under each section, besides the description of the parasites, the symptoms and treatment are detailed so that this work forms a complete handbook on the subject of dysentery. A useful bibliography is appended.

R. T. H.

Alcoholometric Tables. By Sir Edward Thorpe. Pp. xiv+91. (London: Longmans, Green and Co., 1915.) Price 3*s*. 6*d*. net.

THE handy little book of alcohol tables prepared by the late Dr. Stevenson has been out of print now for several years, and a convenient volume, arranged on similar lines and brought up to date, has been a long-felt want. This is fully supplied by the tables under notice, which were compiled under Sir Edward Thorpe's directions at the Government Laboratory. They are based, as regards their main portion, upon the work of Blagden and Gilpin, Drinkwater, Mendeléeff, and the Kaiserliche Normal Eichungs Kommission. The first table shows the percentage of alcohol by weight and by volume, and the percentage of fiscal proof spirit, in aqueous solutions of ethyl alcohol of different specific gravities. The latter are given to four places of decimals, but for the even numbers only (*e.g.*, 0·9172, 0·9174, etc.). The one criticism suggested is whether it would not have been worth while to include the odd numbers as well. True, this would have made the book about half as large again, but it would have saved the user many small calculations.

The other tables serve for the comparison of the spirit values adopted for fiscal purposes in this country with those of the principal foreign countries. They show the indications of Sikes's hydrometer, with the corresponding percentages of British proof spirit, American proof spirit, and alcohol as evaluated on the French, German, and

Tralles systems. They give also the corresponding indications of the hydrometers used in Russia, Holland, Spain, and Switzerland.

All the tables are well arranged, well printed, and well spaced, with figures in large type: this all makes for accuracy and convenience in use.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Rule for Determining Direction of Processional Movement.

THE method of determining the sense of the precession is usually given in the following way:—"If the axis of angular momentum and the torque axis are drawn in the same sense (that is, for the same direction of turning), then the axis of angular momentum sets itself towards the torque axis."

By this method we must imagine the axis of rotation and torque, which cannot be seen directly. By the following method this is not necessary:—

"If you stand at one end of the axle of the gyroscope, it will precess in the same sense to the rotation of the wheel, as seen by yourself." Here, the moment of force due to your own weight determines the tilting couple. According to my experience, this is a very convenient and practical rule for the direction of precession of a gyroscope. W. WATANABE.

34 Waldegrave Park, Twickenham, September 28.

I AM obliged by your courtesy in allowing me to see Prof. Watanabe's communication. He sent me his rule some little time ago, but by an accident which I regret his letter did not receive immediate attention.

I take it that what Prof. Watanabe's very concise statement suggests is the following. Imagine the gyrostat, supported, let us say, at a point on its axis of symmetry, with that axis inclined at an angle θ to the upward vertical, and precessing under a couple produced by a gravity force applied at a point on the axis of symmetry. If that force be due to the weight of an observer standing on the axle and looking towards the spinning flywheel, the axle, with the observer, will be carried round in azimuth in the direction in which he sees the part of the wheel looked at carried by the rotation.

This is quite correct and convenient if it is the upper part of the wheel that is looked at, and if the precession is, as it is almost always taken to be, and usually is, that given by the numerically smaller root of the quadratic equation which determines the steady motion of the gyrostat for a given value of θ. But, except in the case of $\theta=90^\circ$, when the larger root is infinite, it is possible, by properly starting the gyrostat, to realise the precession given by the numerically larger root. This is the "adynamic" precession, so called because to a first rough approximation, this precession, if the gyrostat is rapidly rotating, is independent of the applied couple. In this case, when also θ is greater than 90°, and the roots are therefore opposite in sign, Prof. Watanabe's rule must be reversed. But it is to be noted also that, in these unusual circumstances, neither does the rule hold that the axis of spin follows the couple axis. A. GRAY.

The University, Glasgow, October 7.

The Meaning of "Chincough."

IN the notice (NATURE, October 7, p. 141) of the book, "A Chaplet of Herbs," the expression "chincough" is explained in parenthesis as "(hiccough)." The word is in everyday use in this country, and never in any other sense than the whooping-cough; its etymology being understood as connected with the French *chien* = a dog.

The popularly recognised cure for hiccup in children used to be, and may be still, to "frighten it away" by some sudden and discomposing question. It often proved to be quite efficacious. W. E. HART.

Kilderry, Londonderry, Ireland, October 10.

FELLOWSHIPS FOR INDUSTRIAL RESEARCH.[1]

THE subject of the pamphlet referred to below is one of first-rate importance, especially at the present time of crisis in certain branches of manufacture, the cause of which has been attributed to failure to link science and industry.

The experiment referred to is one devised by the late Prof. Duncan, of the University of Kansas (and later of Pittsburgh). It begins by insisting that technical training should not cut into the full graduate course in pure science. The failure to co-ordinate academic training with industrial methods is attributed to mistakes on both sides. It is urged on the side of industry that current industrial practice is always ahead of text-book presentation, that academic methods are too minute and cumbersome, and that whilst strict scientific accuracy is essential in a pre-graduate course, it must give place to less accurate time-saving processes in the factory.

The university professor is also accused of regarding the utilisation of science for human needs as more or less degrading to science itself, and that in consequence he is careless in selecting a chemist possessing the right qualifications; for as Dr. Duncan asserts, industrial research demands all the qualities which are necessary for success in pure science, together with ability to control workmen.

The case against industry is much more searching. Dr. Duncan considers that the failure on the part of the factory to appreciate the advantage of applied science is due to an incapacity to select chemists, inexperience in dealing with them, and ignorance of the facilities in the way of laboratories and libraries which should be placed at their disposal. He states that he has met with instances of chemists of high training, creative power, and practical character who are overburdened with routine drudgery and subjected to the interference of factory foremen, and are working under an entire misapprehension on the part of the officials of the company as to their possibilities and value. Moreover, it is pointed out that the manufacturer may not know the real nature of the problems which have to be solved, their relative importance, or the kind of knowledge required for their solution. He has no means of judging the qualifications of the men available for his researches

1 "An Experiment in Industrial Research." By T. L. Humberstone. Board of Education: Educational Pamphlets, No. 30. (London: Wyman and Sons, Ltd.) Price 4d.

or the expenditure on laboratories and equipment which the work would entail. He has had no experience of co-ordinating research work with the operations of the factory or of estimating the progress made. In short, though the pamphlet does not say so in so many words, the manufacturer is accused of ignorance of the scientific side of his industry.

Having thus presented the difficulties on both sides, Mr. Humberstone, the author of the report, proceeds to formulate Dr. Duncan's scheme of industrial research fellowships.

"Under this scheme a contract is entered into between the manufacturer and the university in which the object of the research is precisely defined. The contract provides that the fellow selected to conduct the investigation desired shall devote his whole time to the research with the exception of three hours a week, which he may devote to instructional work in the chemical department. The fellow is a member of the university, and pays all the regular fees with the exception of fees for laboratory and supplies, for which the instruction he gives in the university is accepted in lieu, unless in the opinion of the university his demands become excessive, in which case the manufacturer who provides the funds for the fellowship is expected to reimburse the university.

"In some instances the manufacturer makes a specific grant for expenditure on apparatus. The contract further provides that the fellow shall work under the direction of the professor of industrial chemistry, and shall forward to the manufacturer periodically through the professor reports on the progress of the work. The manufacturer agrees to pay to the university an annual sum for the emoluments of the fellow during the tenure of the fellowship, which ordinarily extends to two years."

A clause follows relating to the proprietorship of inventions made by the fellow, providing usually for a payment of ten or some other percentage of the net profits arising from discoveries, to be commuted at the desire of either party for a sum fixed by arbitration, and there are certain other details in regard to the publication and use of the discovery.

The advantages claimed under this scheme are that the university profits by the presence of men engaged in researches, which, though utilitarian in their object, may often throw light on questions of purely scientific interest. The university also secures the services of post-graduate students as instructors, and the influence of such a body of men who are keen on their particular work and enthusiastic as to the value of research, is an asset of considerable value. The manufacturer derives advantage from the resources of the well-equipped laboratories, museums, and libraries, and from the facilities offered to the fellow for consulting the staff of his own and other departments of the university when unforeseen difficulties present themselves, whilst at the same time the manufacturer is free from the responsibility of selecting the specialist (which is done by the university) or of supervising his researches.

The advantages of the scheme to the selected fellow are obvious. He is brought into direct contact with a manufacturer and a specific problem, and carries on his investigation under the advantage of being free from interference by foremen or managers. He has also opportunities of consulting a well-appointed library, of obtaining assistance from colleagues, and occasion to test his process under industrial conditions. Moreover, the researches may be put forward in his candidature for the doctorate of the university. The report concludes with an account of the practical working of the scheme, and the remarkable variety of problems which have been submitted to investigation.

The only point which the writer regards as open to serious criticism is that the industrial research of whatever character, whether connected with organic, inorganic, or physical chemistry or physics, is conducted in a special laboratory under the absolute jurisdiction of the director of the industrial research laboratories, instead of being carried out in that department which is specially concerned with the particular problem. Apart from this, the scheme appears to offer many advantages in the present condition of the scientific industries in this country, as well as in America. Whether it is an ideal scheme is another question. It is true that in Germany there are chemists working out in the university laboratories problems which have an industrial object, but the great bulk of such research is restricted to the splendidly equipped works laboratories. The reason for this is a simple one. The managers are trained men of science (as many are in this country) who know the methods of research and the value of the research chemist. They have no need of a director of industrial research. They are in a position to direct it themselves.

J. B. C.

CONSTRUCTIONAL DATA OF SMALL TELESCOPE OBJECTIVES.

THE National Physical Laboratory has recently published through Messrs. Harrison and Sons a pamphlet with the above title. This has been prepared at the request of the Director-General of Munition Supplies, and is primarily intended for the assistance of manufacturers of optical instruments who are engaged in the production of optical munitions. The glasses on which the calculations are based are in all cases taken from the most recent catalogue of optical glasses issued by Messrs. Chance Bros. and Co., of Birmingham (February, 1915). The comprehensive character of the tables may be gauged from the fact that all the dense flints of this catalogue are severally combined with all the crowns, two dense barium crowns of high refractive index alone being excepted.

Although the theoretical conditions which it is desired to satisfy in the case of these small objectives are identical with those which determine the construction of large telescope objectives, other considerations which are of little importance in the one case can by no means be neglected in the other, and it thus happens that the

objectives described in these tables are not given the forms determined by the astronomical telescope conditions—freedom from colour, central spherical aberration, and coma—but one of these is deliberately sacrificed to enable the crown and flint components to be cemented together. This leads to the consideration of six forms of objective, three of which have the crown lens before the flint and three with these lenses in the reverse order, two forms of each set of three being free from colour and from central spherical aberration, and one free from colour and from coma. Each of these forms is described in a separate group of tables.

With most of the glass combinations one of the forms with the crown lens placed before the flint has the two surfaces of the crown lens of nearly equal curvature, and a set of tables is included devoted to lenses in which these curvatures are exactly equal. Such lenses offer the very considerable advantage when rapid output and low cost is of importance, of requiring only two sets of tools for their production, one set corresponding to the equal curvatures of the crown lens and the surface of the flint lens which will be cemented to a face of the crown component, the other set being, of course, for the second surface of the flint lens.

To each group of tables giving the constructional details of its own particular type of lens is added a table showing the amount of the aberration—coma or spherical aberration, as the case may be—which has unavoidably been retained in consequence of the restraint imposed by the condition that the two components are to be cemented to one another. A glance at these tables shows which form of objective and what combinations of glasses are the most suitable to employ in various circumstances. The physical interpretation to be placed on these quantities is explained in a note which prefaces the tables. For convenience in reference all the tables relating to one form of objective are placed on a single opening of the pamphlet.

The fundamental tables relate to lenses in which the thicknesses are negligible. A second set of tables is added, showing the alterations in focal length produced by standard thicknesses, which are taken to be 1/40th of the focal length for the crown component and 1/80th of the focal length for the flint lens, and also the corrections to the curvatures which are necessary to give the thick lenses the same focal length as those of negligible thickness. For convenience in making such corrections the principal set of tables give the curvatures of each lens surface in addition to their radii of curvature. The foregoing particulars suffice to show that the pamphlet should not only be of immediate use to those for whom it has more especially been prepared, but should prove of permanent value to all who are engaged in the construction of small objectives. It may be obtained from the publishers, Messrs. Harrison and Sons, 45 St. Martin's Lane, London, W.C.; price 2*s*. 6*d*., plus postage.

The laboratory authorities state that it is hoped later to supplement this publication by a further paper dealing with the corrections which may be necessary for object glasses of somewhat larger size. They may also undertake further optical calculations needed to perfect instruments required by the naval and military authorities if it seems to them desirable.

T. SMITH.
R. W. CHESHIRE.

JEAN-HENRI FABRE.

IT is more than half a century since Darwin quoted Fabre in his "Origin of Species" and called him "that inimitable observer." Yet he has been with us and working till the other day—a resolute veteran, in spite of his extraordinarily hard and strenuous life, from which he wrung out the joys of discovery and devotion. In this sense he lived a successful life, and he had other rewards—the appreciative esteem of expert entomologists; the admiration of those who have enjoyed his intimate descriptions of the life and work of insects and his singularly vivid style; the encouragement of good friends, such as John Stuart Mill and Mistral; but one cannot escape the regret that, through imperfections in contemporary social organisation, his genius, which was marked by a unique blend of observing power and sympathetic insight, was through a large part of his life unduly distracted and inhibited by the cares of keeping up the supply of daily bread. Perhaps on his own side he carried the spirit of independence to an extreme. In any case there is a pathetic ring in his own words, a short time ago, about his life, that it "had not been exempt from many cares, nor very fruitful in incidents or great vicissitudes, since it had been passed very largely, especially during the last thirty years, in the most absolute retirement and the completest silence." The ten volumes of the "Souvenirs Entomologiques," many of the best chapters of which have been translated into English, remain as Fabre's lasting monument. They show us an observer of insects, second only to Réaumur, who was able, in a way all his own, "instinct pursuing instinct," as has been well said, to get at the insect's point of view.

After a somewhat disappointing early struggle as a professor at Ajaccio and Avignon, Fabre recoiled from conventionalities and settled down on a little desert corner near Orange, in the lower Rhone, and subsequently at Sérignan, and gave himself up to entomology. His studies were occasionally anatomical and physiological, and he watched many life-histories; but he was pre-eminently the student of animal behaviour. His work is marked by strong vitalistic convictions, organism to him transcending all mechanism; by a belief in instinct as a big underivable fact, quite different from intelligence; and by a strong prejudice against Darwinism, even against evolutionism. "The facts that I observe," he said, "are of such a kind that they force me to dissent from Darwin's

theories." It is not evident that he studied these theories, or those that have developed from them, with the open mind and carefulness with which he approached his insects in the Orange wilderness, but he felt that they were all too mechanical, and perhaps he was not far wrong. He did not, however, criticise constructively, or take account, so far as we know, of evolutionist yet not Darwinian positions, such as that of Samuel Butler, with whom he would have found himself, in his recoil from the mechanistic, in hearty sympathy.

While Fabre's aloofness from evolutionist interpretation must be regarded as a defect in his scientific work, there is surely truth in what has been said, that "in his sense of the dignity of facts; in his high standard of precision; in his appreciation of the trivial, Fabre came, in spite of himself, into fellowship with Darwin." Perhaps he occasionally read too much of the man into the insect—and he was himself as much a man of feeling as a man of science—but he made a big contribution to the interpretation of animate nature by his convincing evidence of its pervasive mentality and purposiveness. Fabre was a Chevalier of the Legion of Honour and a corresponding member of the Institute.

NOTES.

As an outcome of the recent Manchester meeting, the British Association has invited the following gentlement to serve on a committee to consider and report upon the question of fuel economy (utilisation of coal and smoke prevention), from a national point of view:—Prof. W. A. Bone, of the Imperial College of Science and Technology, London (chairman); Mr. E. D. Simon, chairman of the Manchester Air Pollution Committee (secretary); Profs. P. P. Bedson (Armstrong College, Newcastle-on-Tyne), J. W. Cobb and J. B. Cohen (Leeds University), H. B. Dixon (Manchester University), Thomas Gray (Royal Technical College, Glasgow), H. S. Hele-Shaw (London), L. T. O'Shea and W. P. Wynne (Sheffield University), and Richard Threlfall (Birmingham), together with Dr. G. T. Beilby (Glasgow), Mr. Ernest Bury, and Dr. J. E. Stead (Middlesbrough and the Cleveland district). The committee, which is empowered to add if necessary to its members, has been selected so as to include representative chemists, engineers, and technologists from all the principal industrial areas.

We are informed that the council of the University of Manchester has received from an anonymous benefactor the sum of 1368*l.* to pay off the debt which remained on the new extension of the museum that was added recently for the housing of the Egyptian antiquities and of collections of minerals.

An exhibition of photographs in monochrome and natural colours, by Mr. H. Essenhigh Corke, will be open free to the public, on presentation of visiting card, at the Royal Photographic Society of Great Britain, 35 Russell Square, W.C., until Saturday, November 27, daily from 11 a.m. until 5 p.m.

The death is announced, in his eighty-six year, of Mr. Charles Fortey, who was for many years honorary curator of the Ludlow Natural History Society's Museum. He is gratefully remembered by many geologists and palæontologists for the manner in which he made the unique collection of Upper Silurian fossils in his charge available for purposes of research.

The death is announced in *Science*, in his eighty-second year, of Prof. W. Watson, from 1865 to 1873 professor of mechanical engineering and descriptive geometry in the Massachusetts Institute of Technology, and since 1884 recording secretary of the American Academy of Arts and Sciences.

In 1903, at the International Geological Congress, Mr. Emmons, supported by the late Prof. E. Suess, proposed the establishment of an institute for the study of geological physics. A preliminary meeting was held on October 14, with Prof. Benjamin Moore in the chair, at which it was decided to form forthwith a society for the encouragement and study of geological physics, commencing with the subject of segregation in rocks. Under the presidency of Prof. Moore the society hopes to do good work by the exchange of specimens, photographs, and literature between its members. An annual subscription of 2*s.* 6*d.* has been fixed for the first two years. Communications are invited by the hon. sec. *pro. tem.*, Mr. G. Abbott, 2 Rusthall Park, Tunbridge Wells.

We mentioned in our issue of July 8 (p. 514) the case of an officer who had sent to the Natural History Museum at South Kensington the skins of some small animals trapped by him in the trenches in northern France. Dr. Ugolini, of the Royal Technical Institute at Brescia, Italy, writes to tell us that one of his four sons serving in the Italian Army, a doctor of natural science, has been able amid the perils of war on the high mountains of the Trentino, to make valuable geological observations, and to collect and dry plants of particular botanical interest. The keen naturalist always makes use of opportunities of acquiring knowledge; and no doubt many other instances could be given of the persistence of this ruling passion under conditions in which scientific work would scarcely be expected.

The death is announced, in the *Engineer* for October 15, of Mr. J. S. Graham, the general manager and a director of the Northumberland Shipbuilding Company, Ltd., of Howden-on-Tyne. Mr. Graham was born at Kingborn, Fifeshire, in 1864, and had varied experience in shipbuilding. A notable piece of work under his charge was the construction and delivery of the Havana pontoon dock. During the Spanish-American war he returned to this country, where he joined the Northumberland Shipbuilding Company in 1898.

The Aristotelian Society will begin its session on November 1 with the inaugural address by the president, Dr. Wildon Carr, on "The Moment of Experience." At the second meeting on December 6, Lord Haldane will read a paper on "Progress in Philosophical Research." Some papers of specially scientific interest are announced, including one by Prof.

Whitehead, on "Space, Time, and Relativity," and one by Prof. Nunn, on "Sense-data and the Physical Object." There will be two symposia, one on "Recognition and Memory," and one on "The Theory of the State."

THE death is announced, at eighty-two years of age, of Colonel T. E. Vickers, C.B., who played a leading part in the development of the great steel firm of that name. He was (says the *Times*) among the pioneers in the early 'seventies of the open-hearth process of melting steel, and achieved a great success, notwithstanding the paucity of scientific knowledge and the lack of instruments for ensuring precision in regard to temperature, etc. The River Don works, now one of the great industrial establishments of the country, were inaugurated in 1866, in order to meet the increased demands resulting from early successes, and since then developments have followed each other in rapid succession in connection with heavy forgings, gun-making, armour manufacture, shipbuilding, and corresponding industries, so that long before Colonel Vickers's retirement in 1909 the firm had become one of the most renowned in the world. Colonel Vickers was awarded the Howard quinquennial prize by the Institution of Civil Engineers, "in recognition of the part taken during his career in developing and improving the production of steel for important engineering purposes."

IN view of the possibility of fires which may arise from further attacks by hostile aircraft, the Commissioner of Police of the metropolis directs attention to the warning published in June last, recommending that a supply of water and sand be kept readily available for dealing with incendiary fires. It is suggested that chemical liquid fire extinguishers should not be purchased without a written guarantee that they comply with official specifications. The specification issued by the Board of Trade (Circular 1560) has reference to the ordinary type of extincteur in which water charged with carbonic acid gas is used as the extinguishing liquid; it indicates the chief points of construction, testing, and maintenance to which attention should be directed in connection with such apparatus. As regards dry powder fire extinguishers, the public is warned that no trust can be placed in them for effectively controlling fires such as are likely to be caused by bombs, whether explosive or incendiary. In dealing with such outbreaks of fire, the prompt and intelligent use of water or sand, or of both, is considered to be the best, simplest, and most economical procedure.

WE regret to announce the death of Dr. Charles Callaway, of Cheltenham, who was one of the pioneers in the study of the Archæan rocks of the British Isles. Dr. Callaway was born at Bristol in 1838, and was educated for the Nonconformist ministry, which he afterwards relinquished for education work and geology. In 1874, when he read his first paper before the Geological Society, much remained to be done in distinguishing the Cambrian rocks from those of earlier date, and in establishing the broader grouping of the latter. The extent of his geological work is shown by the fact that more than twenty papers by him have been published in the Quarterly Journal of the Geological Society, descriptive of the older rocks of Shropshire, the Malverns, Anglesey, Assynt and other regions in the north-west Highlands of Scotland, and parts of Ireland. In some of these regions he was the first to identify the occurrence of subdivisions of the Cambrian rocks and to ascertain their relation to the Archæan groups. In the latter he introduced the terms Uriconian and Longmyndian. The value of his work was recognised by the award to him in 1885 of the Wollaston Fund of the Geological Society, and in 1903 by the award of the Murchison medal. Among the more important of his papers in the Quarterly Journal of the Geological Society may be mentioned "The Pre-Cambrian Rocks of Shropshire" (1879–1882) and "The Age of the Newer Gneissic Rocks of the Northern Highlands" (1883), but many others have been published in the *Geological Magazine* and in the Proceedings of the Cotteswold Naturalists' Field Club, of which he was a past-president. Dr. Callaway was also a writer on ethical subjects.

To the October number of the *Fortnightly Review* Mr. J. B. C. Kershaw contributes an article on the scientific and engineering aspects of the war. It is pointed out that this is the first great war in which the striking advances of scientific knowledge of recent years have been allowed full play, and how great has been the influence in every direction. The subject is dealt with under four headings—the petrol motor and its application to land transport and aviation; smokeless powders and high explosives; the use of inflammable liquids and poisonous gases; the legal and moral aspects of some of these recent developments. The combination of high power with lightness in weight of the petrol motor rendered possible, first, the automobile, and then the dirigible balloon and aeroplane. The automobile has revolutionised the question of supplies to the front, and warfare on its present scale would otherwise have been impossible; troops fighting in districts long since denuded of food supplies are remarkably well catered for, and the inhabitants saved from starvation. The haulage of heavy siege guns, the use of armoured motor-cars, the rapid movement of troops, and the efficient motor ambulance service, all emphasise the utility of the petrol motor. The results from aviation are of immense importance—in directing and controlling artillery fire, and in observation work. Discussing explosives, the writer, having described briefly the compositon and characters of smokeless and high explosives, points out how the invisibility on discharge in daylight enables batteries to be hidden, and how the sniper is able to perform his deadly work undetected. The section on the use of inflammable liquids is largely historical, "Germany's step forward in this direction, however, in reality is a step backwards towards barbarism," the use of such methods dating back to very early times.

A VALUABLE memoir on the evolution and morphology of the Palæozoic star-fishes and brittle stars has just been published by the United States National Museum (Bulletin 88). The author, Mr. Charles Schuchert, re-

marks that throughout the Cambrian system not a single star-fish has yet been discovered, from which he infers that the skeleton was not evolved until the Lower Ordovician, "where they will surely be found." The Ordovician Hudsonaster he regards as the ancestor of the asterids of the Phanerozonia type. Numerous diagrams in the text and several excellent plates illustrate this difficult theme.

THE autumn number of *Bird Notes and News* contains much readable matter in regard to the effect of the war on bird-life in France and Flanders. Swallows returning this spring to their accustomed nesting sites only too often found them reduced to a heap of ruined masonry. In such cases huts erected for military purposes have been adopted as substitutes. This fact shows the tenacity with which these birds cling to their old haunts. Birds roosting between the lines of the opposing forces have on more than one occasion given timely warning to the sleeping men of the near approach of poison gas fumes, by the rustle of their wings and low cries as they passed over our trenches. Except, indeed, when actually within the zone of fire the birds have shown themselves strangely indifferent to the strife around them. Some valuable data in regard to birds in relation to agriculture are also given in this number.

THE *Psychological Bulletin* (vol. xii., No. 8) contains a valuable summary of recent literature on habit formation, imitation, and higher capacities, in animals. The difficult task of summarising the work done in this field has been skilfully performed by Mr. John Shepard. All kinds of animals have been experimented on, from fiddler-crabs to monkeys. A series of studies carried out with pigs, by Messrs. Yerkes and Coyurn, on the multiple choice method, convince the authors that they have established an approach to "free ideas" in that animal. Though visual and kinæsthetic factors in the main determine the responses, the pig, they consider, is more independent of the particular situation than is the crow. The same number also contains a similar summary, by Mr. K. S. Lashley, on sensory discrimination in animals. The experiments recorded are mainly those concerned with responses to light, sound, touch, and smell. Echinoderms, molluscs, and insects, frogs, birds, and various mammals furnished the material for these investigations.

THE October number of *Irish Gardening* contains some extracts of letters written in August by Mr. C. F. Ball, the editor, to Sir F. W. Moore, in which some interesting accounts of the vegetation on the Gallipoli peninsula are given. It is with great regret that we have received the news that Mr. Ball was recently killed in action in the Dardanelles. Mr. Ball, who received his horticultural training at Kew, was assistant to the keeper of the Royal Botanic Gardens, Glasnevin, and, on the outbreak of the war, volunteered for service, and enlisted in the 7th Royal Dublin Fusiliers.

THE new garden plants described in English and foreign botanical and horticultural publications during the year 1914 are brought together in a complete list in appendix iii. of the Kew Bulletin. Some 350 new plants, varieties and hybrids, are enumerated. In the case of hybrids the parentage, where known, is given, and the place of origin. In the case of new plants a brief description is appended, the country of origin stated, and the name of the introducer. This publication, which is produced annually at Kew, should prove indispensable to the maintenance of a correct nomenclature, and affords valuable information in a concise form respecting new plants under cultivation, abstracted from a very large number of scattered publications.

A CENSUS report on the mosses of Ireland occupies No. 7, section B, of vol. xxxii. of the Proceedings of the Royal Irish Academy. As far as possible the earliest and latest known records are given for each species, except in the case of the commonest and widely distributed species. The divisions of Ireland adopted in Mr. Praeger's "Irish Topographical Botany" are used. Since the publication of David Moore's "Synopsis of the Mosses of Ireland" in 1872, 118 mosses new to Ireland have been recorded, and forty-two of these are recorded for the first time in the present report. The list of records is preceded by a very interesting account of the progress of muscology of Ireland, giving details of the various collectors and their contributions. John Ray is the first to mention mosses in Ireland, and these were probably collected by William Sherard, of Oxford. To David Moore our knowledge of the mosses of Ireland is very largely due, and he added sixty-seven species and varieties to the Irish flora. A useful bibliography of papers dealing with Irish mosses is also included in the report.

THE second part of Father E. Blatter's "Flora of Aden" has recently been published as vol. vii., No. 2, of the Records of the Botanical Survey of India. Part i., which appeared in 1914, consisted of a general account of the flora and of the physical aspects of the country, and was accompanied by a large scale map of the district; the present part deals entirely with a systematic account of the flora. A synopsis of the natural orders—Ranunculaceæ to Urticaceæ—is given, and the families, genera, and species are fully described; keys are also given for the genera and species. The indigenous species number 250, distributed under 138 genera; 33 of these species belong to the grasses, 32 to the Leguminosæ, 18 to the Capparidaceæ, 13 to the Euphorbiaceæ, 11 to the Chenopodiaceæ and Boraginaceæ, and 10 to the Compositæ. Most of the other families are represented by only one or two species. It is of interest to notice that the three plants belonging to the family Burseraceæ found at Aden are the well-known myrrh, *Commiphora abyssinica*; balm of Gilead, *Commiphora opobalsamum*; and frankincense, *Boswellia Carterii*, about which Father Blatter gives some interesting historical details. Much of our information about the flora of Aden is due to the collections of passing travellers, who may have spent only a few hours on shore, but their labours brought together in systematic form make a valuable contribution to our knowledge of the little-known vegetation of southern Arabia.

THE origin of certain valleys in Cleveland, Cumberland, and elsewhere, which have generally been attributed to overflow streams from ice-dammed lakes, has been investigated by Prof. T. G. Bonney. His conclusions are published in a pamphlet ("On Certain Channels," Bowes and Bowes, Cambridge, 1915). Prof. Bonney contends that these channels are relics of an ancient drainage system, in the case of the Cleveland ones, post-Jurassic, if not post-Cretaceous, and in the case of the Cumberland ones, probably pre-Triassic; but, at any rate, in all cases long anterior to the Ice age.

IN the Bulletin of the American Geographical Society (vol. xlvii., pp. 672–80) Prof. R. de C. Ward returns to the discussion of the climatic subdivisions of the United States. Such divisions must be chosen in relation to cyclonic and anticyclonic tracks and movements, and local and characteristic weather distribution around high and low pressures. Changes in climate in the United States are met with in going east and west, and not north and south. The climatic subdivisions must therefore be separated by meridional and not latitudinal lines. East and west boundaries are largely arbitrary. The main divisions arrived at are five, an eastern province and a gulf province, both bounded on the west by the 2000-ft. contour, that is, about 100° W., a plateau province extending west to the generalised line of the main Rocky divide, a plateau province bounded on the west by the Sierra Nevada-Cascade divide, and a Pacific province. The last three are subdivided into northern and southern regions about 43° N.

THE use of a new type of submarine for hydrographical work is described by Mr. Simon Lake in the *Scientific American* (vol. cxiii., No. 13, September 25). The submarine employed is connected with a surface vessel by an access tube. Power is transmitted from a dynamo on the surface vessel to the submarine, which is provided with a single pair of toothed driving wheels at its bows, capable of being turned in any direction. From the air chamber in the submarine a diver can leave the vessel to examine the sea bottom. The author advocates the use of this type of vessel in pairs for harbour contouring. Two such vessels, each with its surface vessel, and linked together by two wires, the upper for telephoning purposes, and the lower one to locate obstructions, steer parallel courses half a mile apart. Any obstruction between the submarines would cause a pull on the wire, and the rock could then be located by one of the vessels steering towards it, reeling in the wires as it went. Mr. Lake omits to say whether his method has proved practicable. If successful it would certainly give more accurate hydrographical data than can be obtained by the sounding machine alone.

AN earthquake was felt throughout a large part of Cumberland and in the surrounding counties on October 2 at about 3.15 a.m. The disturbed area, which extends from Newcastleton in Dumfriesshire on the north to Langdale and Troutbeck on the south, and from Silloth on the west to beyond Kirkoswald on the east, is about fifty-five miles long from north to south, and about thirty-seven miles wide, and contains about 1600 square miles. It thus seems almost co-extensive with the disturbed area of the Carlisle earthquake of July 9, 1901 (Quart. Journ. Geol. Soc., vol lviii., 1902, pp. 371–6). This earthquake, according to Dr. Davison, was a twin earthquake, originating in a long deep-seated fault directed N. 5° E., underlying the complicated formations of the Lake District. The principal focus was situated seven miles south-south-west of Carlisle, the other more than twenty miles to the south.

PROF. A. McADIE discusses temperature inversions in relation to frost (Blue Hill Meteorological Observations, Cambridge, U.S.A., 1915). He seems to find more difficulty in explaining the radiation frosts that occur in sheltered valleys than there really is, for the commonly given explanation is quite simple and meets the facts so far as they are known perfectly. The first requirement is free radiation, which means absence of cloud of any kind and also absence of water vapour in the overlying air strata; the second is absence of wind. Given free radiation, the ground is rapidly cooled, and imparts its coldness to the bottom layer of air. When this occurs on the summit or slope of a hill the cold air simply runs off down the slope just as water would do, and its place is taken by warmer air from above; hence on the summit or slope there is no great fall of temperature. But on a plane or in a valley bottom the case is different, because the chilled air cannot run off and the chilling effect of radiation is continued upon the same air, which therefore reaches a low temperature. Under such conditions there is naturally a sharp temperature inversion a short distance above the ground. Absence of wind is a further requisite because wind would mix up the different layers of air, thus warming the lower and cooling the higher, but with free radiation at night there is generally a calm on the surface, though there may be a good breeze a little way up. Prof. McAdie then discusses the artificial means by which damage to growing crops may be reduced or avoided.

PROF. E. BUCKINGHAM, of the Washington Bureau of Standards, sends us several recent papers by him dealing with the principle of similarity and the method of dimensions as applied to the formulation of equations representing physical results. Two of these papers are published in the *Physical Review*, iv., 4 (October, 1914), and the Journal of the Washington Academy of Sciences, iv., 13 (July, 1914). In addition, we have a communication to the American Society of Mechanical Engineers, read in June, 1915, and a letter to the *Electrician* (January 15, 1915) criticising Becker's formula for the windage of fly-wheels, on the ground that the terms are not all of the same dimensions. It is remarkable how prone not only students, but experienced mathematicians and engineers are to write down equations which are obviously of wrong dimensions. After giving numerous illustrations of the method, Prof. Buckingham points out that the method is purely formal and algebraical. If certain quantities and no others are connected by a physical relation, the equation connecting them must necessarily be of a certain form. Any mistake must be due to overlooking one of the

variables on which the result depends. The process cannot supply any new facts. We only get out what we put in, but this is generally in a much more useful form than the original assumptions. It is to be hoped that a study of Prof. Buckingham's papers may lead to a diminution of the mass of unwarrantable deductions and unsound formulæ that now finds its way into scientific and more especially technical literature. We need only instance the rule that "no purely arithmetical operator such as log or sin can be applied to an operand which is not a pure number," as one of the laws which is most often overlooked.

The leading article in *Engineering* for October 15 discusses the second and final report, just issued, of the Departmental Committee on bulkheads and watertight compartments presided over by Sir Archibald Denny. The report deals with passenger steamers trading to the Continent between the limits of Brest and the Elbe, in the channels surrounding the British Isles, also those plying on short excursions round the coast, and on rivers, estuaries, lakes, and canals. The fundamental principle underlying the recommendations is the same as that in the first report dealing with ocean-going vessels. A difficulty arises in dealing with the classes of ship to which the second report refers, owing to the overlapping in the principal features of design of the respective types; also the sizes of vessels vary greatly. These considerations involved difficulty in stringently applying rules general to all types. It seems probable, however, that the general recommendations of the committee will be acceptable to all; no doubt the exceptions will be considered on their merits by the authorities. It is of interest to note that Channel steamers are treated more severely than oversea passenger steamers in the matter of bulkhead doors—doors worked from the bridge alone are permitted.

Mr. John Murray's new announcements include:—Vegetable Fibres, by Dr. E. Goulding (in the "Imperial Institute Handbooks"); A History of the Gold Coast and Ashanti from the Earliest Times to the Beginning of the Twentieth Century, by W. W. Claridge, 2 vols.; and new editions of The Study of Animal Life, by Prof. J. Arthur Thomson, illustrated, and Geometry: an Elementary Treatise on Theory and Practice, by S. O. Andrew.

OUR ASTRONOMICAL COLUMN.

Selenium Cell Photometry of δ Orionis.—Some years ago Prof. Joel Stebbins announced that measures of the light of δ Orionis by means of the selenium photometer indicated that this remarkable stellar system was also an eclipse-variable, although visual observation had failed to establish any alteration of magnitude. An extensive series of measures of the feeble fluctuations of its light was secured during the years 1910–11–12 (*Astrophys. Journ.*, September). The only spectroscopic orbit then available was Hartmann's memorable determination which revealed the first example of fixed calcium lines. These elements were used in deducing the light-curve, but the complete discussion was held up whilst Prof. R. H. Curtiss re-investigated the radial velocity variations, and these new elements have been employed in the discussion of the dimensions of the system. The variation of brightness is only 0·15m., of which 0·08m. is considered due to eclipses. The presence of a resisting medium such as the calcium envelope suggested by Hartmann's discovery would help to explain the brightness near periastron, which is a feature of the light-curve. It is only possible to fix limits for the dimensions of the system. The minimal values possible for the radii of the two bodies are 5 times and 1·4 times solar, and the mean density of the system is found to be 0·006 solar.

The Plane of the Solar Motion.—Criticism of the hypothesis of star-streaming has led to several attempts to develop a gravitational idea of the stellar universe. Thus Prof. H. H. Turner, in 1912, and just about a year earlier Prof. von S. Oppenheim, both suggested that stellar motions were orbital in character, the stars oscillating or revolving about an ideal centre distant from the sun. The solar system itself contains a model closely representing Prof. Oppenheim's conception in the swarm of minor planets viewed from the earth. This fact has again been made of use in an investigation of the solar motion (No. 4813, *Astronomische Nachrichten*), affording means of testing the formulæ employed in deducing the plane of the sun's path from astrometric data by permitting a determination of the known plane of the earth's orbit from the geocentric movements of the minor planets. Ephemerides of 265 minor planets gave mean motions, etc., of the bodies comprised in every two hours of R.A. Reduction by the Bessel-Kobold method hence gave twelve pairs of values of the position of node and inclination of the earth's orbit; eleven showed fair agreement, and yielded the highly satisfactory mean values $\Omega=0^\circ\ 44'$, $i=22^\circ\ 0'$, instead of 0° and $23^\circ\ 27'$ respectively. The application to the case of the solar motion was made on the basis of data from Charlier's second memoir. The resulting mean values for all Charlier's areas taken together were $\Omega=234^\circ\ 45'$ and $i=50^\circ\ 15'$, corresponding solar apex R.A. $267^\circ\ 58'$, declination $+31·56$; whilst for the galactic areas considered apart the mean values were $\Omega=245^\circ\ 30'$ and $i=58^\circ\ 25'$, apex R.A., $261^\circ\ 4'$, declination, $+23^\circ\ 27'$. Charlier's values were based, it may be recalled, on the proper motions in the P.G.C. of Boss.

Displacement of Photographic Stellar Images.—A curious announcement by M. J. Comas Sola (*Astr. Nach.*, 4814) states that among the stars recorded in successive slightly displaced exposures on the same plate and stellar region, occasionally some pairs of images indicate considerable real or apparent movement in the corresponding star. An example is given. It is added that it is extremely rare that such a displacement appears twice in the same star.

The Solar Eclipse, August 21, 1914.—Prof. Störmer, together with several colleagues, went to Vefsen to observe the eclipse (*Vid. Selk. Forh.*, No. 5, 1915, Christiania). The observers took up stations at Laksfors and 35 km. to the south at Svennigviken, prepared to secure, should the opportunity arise, parallax photographs of auroræ. Favoured by fine weather and clear skies, unfortunately no auroræ were seen, but the cameras were used in taking a large number of snapshots of the corona, including seventy exposures with a kinematograph. Considering the extremely small scale of the pictures, the form of the corona is very well shown in the reproductions.

UPPER AIR TEMPERATURES.[1]

THIS interesting publication of fifty-eight pages gives an account of some fifty to sixty ascents made at Batavia, Java, and over the neighbouring seas. Batavia lies in the latitude of 5° S., and observations from a place so near the equator are of especial value; these observations also were designed for the purpose of giving information on several interesting points.

The first half of the book gives the detailed account of each ascent, that is to say, the temperature and relative humidity at each 100 metres both on the ascent and descent, and the second half discusses the results obtained. The first point discussed is the thickness of the land wind at night and the temperature inversion. The highest temperature was found at 170 metres, and the depth of the land breeze was 130 metres. The high pressure which prevails over Australia in winter, the winter, that is, of the southern hemisphere, sometimes stretches as far northwards as Batavia, and interesting figures relating to one of these periods are given. Very similar conditions seem to prevail there as in Europe in anticyclonic areas; on rising from the surface, a decrease of temperature with an increasing humidity is met with, but at a height between 2·0 and 3·0 km. excessive dryness with a temperature inversion, or at least a great slackening in the temperature gradient, occurs.

These observations do not depend on kite or balloon observations alone, since the summits of some of the mountains are high enough to give similar records.

In England, the dreary type of anticyclonic cloud that so often covers the sky for days together in winter nearly always, perhaps always, lies just under a sharp inversion of temperature and a layer of excessively dry air, but the height of this inversion seldom reaches 2 km. In Batavia, the cloud layer is replaced by a sheet of moist air in which small cumuli prevail (in the daytime). In both cases the damp and the dry strata are sharply divided, and Dr. Braak discusses the reasons of this arrangement. There cannot be much doubt that the extreme dryness is due to the air having descended from a colder, and therefore dryer, level, dryer, that is, in the sense of having a smaller amount of water vapour; but dry air, as Tyndall pointed out long since, cannot radiate or absorb radiation with any freedom. Probably radiation from the vapour of the damp strata, which can occur freely through the dry air above, has a good deal to do with the formation of the cloud, especially the sea, but they are not numerous enough to show the magnitude with any certainty.

The daily temperature change by day over the sea and the nightly change over the land are also discussed. Dr. Braak finds over the land in the early afternoon a gradient from 0 to 300 m. of 1·34° per 100 m. Over the sea he finds practically no daily change at the sea surface, the amplitude being about one-third of a degree, but the value increases somewhat up to 600 m. The observations suffice to show that there is little daily change of temperature over the sea, but are not numerous enough to show the magnitude with any certainty.

Some interesting remarks are made on the fall of temperature at night, and on an irregularity in the change. The double daily oscillation of the barometer in low latitudes is quite sufficient to produce measurable changes of temperature. It is so commonly stated that the adiabatic change of temperature in air is produced by change of height that one is apt to overlook the fact that change of height by itself is absolutely without effect upon temperature, and that the rise or fall is due to pressure changes only, change of pressure being usually, but by no means always, due to change of height.

A MANX TRIBUTE TO EDWARD FORBES.

THE London Manx Society has issued a report of the meetings held in London on February 13 to celebrate the centenary of the birth of Edward Forbes. The report ("Edward Forbes, Great Manx Naturalist, Botanist, Geologist, Zoologist," 45 pp., 1s.) contains an address by Sir Archibald Geikie, Forbes's biographer, on his life and geological work, appreciations of his zoological work by Prof. Ewart, Prof. McIntosh, and Prof. Herdman, and of his botanical work by Prof. Bottomley; also contributions by Prof. Boyd Dawkins, Mr. Whitaker, and Dr. J. W. Evans, a letter by Mr. Ulrich on behalf of the Palæontological Society of the United States, and the words of Forbes's "Dredging Song." Forbes was born in 1815 in the Isle of Man, and was educated in Edinburgh; in 1841 he was appointed naturalist to H.M.S. *Beacon* during her survey of the Ægean Sea and coasts of Asia Minor. The following year he became Professor of Botany at King's College, which he held, for part of the time, together with the appointments of Palæontologist to the Geological Survey and Lecturer on "Natural History as applied to Geology" at the Royal School of Mines, until his election to the chair of Natural History in Edinburgh in 1854. His death a few months later was, according to Sir Archibald Geikie, "one of the most grievous losses which British science has sustained in our time." His work was remarkable for its wide range, brilliant originality, and philosophic insight. Huxley wrote of him in 1851 that "he has more claims to the title of a philosophic naturalist than any man I know in England." Some of his conclusions on the relations of the British flora to fauna were rejected by his contemporaries and immediate successors, but, according to Prof. McIntosh and Dr. Scharff, they have been established in the main. Mr. E. V. Ulrich, of Washington, reports that Forbes's teaching has "exerted a profound influence on palæontologists the world over," that the principles he enunciated now "assume a commanding importance," and that probably no British author on his subjects has been more followed and quoted in America than Forbes. Forbes was a man of great literary distinction; he was a first-class humorist, and a frequent contributor to *Punch*; and Sir Joseph Hooker has recorded that owing to his talents and his personality "he was beloved and admired beyond any natural historian of his day."

EDUCATION AND INDUSTRY.[1]

I.

THE British Association, by establishing Section L, has recognised education as a branch of science and made provision for its advancement.

But education—I am speaking of that part of it in which human educators intervene—is still regarded as belonging to politics and literature, rather than to economics and physiology. To many people the very title of this paper, "Education and Industry," will appear incongruous. Is there not a great gulf fixed, say they, between hazy views of education high in the clouds above, and the hard facts of science or technology far in the depths beneath?

1 Abridged from a paper read to the Educational Science Secti n (L) of the British Association on September 11, by Principal J. C. Maxwell Garnett.

And yet the intimate relation of education to industry is obvious enough. Of all that goes to make industry possible, let alone prosperous, the human element is the most important. We are careful to select suitable land, we know that capital or credit is essential to us, and we take pains to see that our capital is represented by the most suitable works, machinery, and material. But we commonly take little interest in producing the necessary men to undertake, design, direct, and manipulate the work.

It is true that industry exists for men, not men for industry; and it follows that to train men for industry cannot be the whole end of education. How far the specific training of men for their particular occupations is legitimate can only be decided when we know what the true aim of education really is. Upon the answer to this fundamental question educators are not agreed.

But agreement should not be altogether out of reach if only we would treat education as a natural science. We should then endeavour to keep our thought about education in the closet possible touch with facts, especially physiological facts; we should think and speak, not only of the mind or soul, but also of the cortex of the cerebrum, through which alone the soul can be reached by human educators. When facts are available we should use them, and follow George Eliot's advice not to replace them by metaphors, or mixed metaphors like that of the broad foundation of general culture. When facts are not available we should, if possible, ascertain them by direct experiment; and, if that is not possible, we should have faith—that is, we should ascertain the facts indirectly by acting on an hypothesis with a view to its verification or modification by subsequent experience. That is how progress has been made in other branches of knowledge, and that is how the advancement of the science of education must also be effected. Moreover, the ground so won must be consolidated by the use of some esoteric or symbolic language; for at present our most precise conceptions, being expressed in words that are used every day with many different meanings, receive from each of our hearers or readers a different interpretation.

Consider, for example, the word "character." Perhaps the most generally accepted statement of the aim of education is that of the opening sentence of the introduction to the public elementary school code: "The purpose . . . is to form and strengthen the character. . . ." But this statement fails to produce any clear conception, because it does not define "character," a word which means different things to different people, and which to most people, perhaps, conveys no clear meaning at all. If, however, we reflect that since two men who, when placed in the same circumstances, always did the same thing, would, for practical purposes, be indistinguishable, we realise that men are characterised by their actions: by their fruits they are known. If then we inquire what it is that determines an individual's actions we find—as I have attempted to show in a recent paper [2]—that in addition to the sensory stimuli arising from the environment of the moment, the determining factors are interest, instinct, and will, together with the habits they have helped to form. These, then, are the foundations of character. A further inquiry shows that, if character is to be strong, two conditions must be fulfilled: in the first place, interest must be single and wide, combining the whole range of the individual's experience into one group of inter-associated ideas and including central ideas which strongly move the emotions (instincts); and secondly, the will must co-operate with this single wide interest and its central group of instincts in guiding thought and action.

2 Published in *Manual Training* for May, 1915.

It follows that if the purpose of education is to form and strengthen character, the proximate aim of education must be to develop a single wide interest—a single complex of inter-connected neurograms.

If the citizens we are educating are to have characters that are not only strong, but also good—that is, if each citizen is to be anxious to serve his neighbours—the emotional element at the heart of his wide interest must be rich in brotherly love. Education without religion is impossible.

If the individual citizens are to be not only anxious, but also able, to serve each other, they must be prepared to divide labour among themselves so as to minister to the economic well-being of the community. The more a man's knowledge or skill differs from that of other people the better in general can he serve his fellow-men. As the occupations of different individuals must differ, and as all the ideas that come to each in the course of his daily work are to form part of his single wide interest, it follows that the single wide interests of different individuals must differ according to their different occupations; and the great interest which each man will then take in his work will incidentally make for his economic efficiency. It is true that these single wide interests must also overlap, so that different individuals may share as far as possible each other's interests and have at least their interest in the State in common. The extent of this overlapping of interests should be limited only by the consideration that during the educand's last two or three years at school—or, if he proceeds to college, then during his university course—his education should have the specific aim of preparing him for his particular work in life, including not only the work for which he is paid, but the whole of what Kim would call his "great game." The need for this application to education of the principle of continuity, so familiar in other branches of natural science, has been thus expressed by the Board of Education's Consultative Committee: "The nearer a pupil is to his entrance into life, the more steadily must the actual practical needs of his occupation be kept in view, and the more decided, therefore, must be the bent of his education to that end." [3]

Finally, education must train the will. The power of the will to focus attention—to direct nerve impulses into a particular system of nervous arcs—is the supreme intellectual faculty, and the only faculty that can be trained. Whoever is to have most creative or abstract thinking to do, most needs this skill in thinking.

II.

These conclusions have been separately proclaimed by several high authorities.

"Milton," said Prof. Perry last year from the presidential chair of this section, "taught me the true notion of education, that the greatest mistake is in teaching subjects in water-tight compartments" [4]; in fact, education must aim at building up a *single* wide interest.

"Thorough knowledge of one subject and practice in it," said Goethe, "produces higher culture than incomplete knowledge of a hundred subjects." [5]

Ruskin had no doubt about the need for specific education. "The idea," he wrote, "of a general education that is to fit everybody to be Emperor of Russia . . . is the most entirely and directly diabolical of all the countless stupidities into which the British nation has of late been betrayed." [6]

"The whole evolution of educational theory," according to Prof. Adams, "may be said to be a

5 Quoted by Dr. Kerschensteiner, "Schools and the Nation," p. 256.
6 "Fors Clavigera," p. 254.

great sweep from specific education back to specific education, through a long period during which formal training held the field."[7]

Finally, William James maintained that "The faculty of voluntarily bringing back a wandering attention over and over again, is the very root of judgment, character, and will. . . . An education which should improve this faculty would be the education *par excellence*."[8]

III.

We shall now assume the truth of these conclusions and proceed to discuss the problem of so educating every individual that he shall possess, in the first place, the single wide interest which his particular service to the community most needs for its efficiency; and secondly, skill in thinking—the capacity of voluntarily focusing his attention.

We have first to investigate the qualities—the type of single wide interest and the degree of skill in thinking—required by those who are to be engaged in various classes of industrial occupation; and afterwards to indicate a means of developing the required qualities in a sufficient number of persons, selected on account of their innate aptitudes for each different kind of work.

The first classification to suggest itself is that of the various branches of industry, such as engineering, building, chemical manufacture, the textile industry, and the like. But the qualities required in the manager of an engineering works have more in common with those needed by the manager of a chemical works or of a cotton mill than with the qualities sought for in the lowest grades of labour employed in any of these industries. In the same way the designer of electrical machinery will generally have more in common with the professional physicist than he has with the engineering tradesman who makes what he designs.

We shall find it convenient to adopt the following classification :—

Class A.—Industrial statesmen; chief designers; research engineers, chemists, etc.; consulting engineers, etc.

Class B.—Works managers and heads of departments; junior members of designing, testing, and managerial staff.

Class C.—Foremen and leading hands; skilled tradesmen.

Class D.—Machinemen and repetition workers; unskilled labourers.

No essential discontinuities are to be imagined between these classes; nor are the occupations named to be regarded as forming complete lists of the classes of work they are intended to indicate.

We have already remarked that every occupation includes that of citizen. We have next to consider the special, or distinguishing, features of each different class of occupation.

It is clear that each class is concerned, in the course of daily work, with a greater *variety* of ideas than the class next below it. Accordingly, trains of thought of members of class A must on the average be fresher, and therefore less governed by habit, than those of members of classes B, C, or D. "The controllers of the great industry," writes Mr. Graham Wallas, "are always on the look out for that type of man whom Americans call 'a live wire.' For such a man secretaries and typists and foremen carry on all that punctual performance of habitual acts which took up so much of the time and labour of a merchant or manufacturer even fifty years ago. He is set to form a habit of non-habituation. . . ."[9] Such a man requires more emotional drive than one who is engaged in mere routine work. And since his ideas cover so wide a range, they are not so naturally associated together as those which their daily work brings to members of classes B or C or D. He therefore needs to weld his various ideas into a single wide interest by making voluntary associations between them; and in order to make such associations, especially between dissimilar ideas, he needs skill in thinking.

So, then, class A requires a wider interest, a stronger emotional element in that interest, and more skill in thinking—but not necessarily more pay—than class B, class B than class C, and class C than class D.

Let us now look more closely at each of these classes. The first named on our list is that of the industrial statesman. We know him already as the captain of industry. But he has lately changed his name, for the title of captain does not indicate with sufficient clearness the fact that the head of a great industrial firm must needs concern himself with much that is happening outside the establishments which he controls. Not only must he be familiar with the state of the markets from which he draws his supplies and in which he disposes of his products, but, by grasping the significance of economic, social, and political changes all over the world, he must be able to foresee opportunities for developing his business according to a far-reaching policy, and to indicate the lines of technological research which are most likely to lead to such developments. Work of this kind involves the widest sort of knowledge. But beware of the professional administrator who is prepared to administer anything at a moment's notice. The statesman—whether industrial or not—must possess, in addition to a wide range of knowledge and much skill in thinking, a very special interest in the particular concern he is directing, whether that concern is his own small business or an empire the destinies of which are under his control. He must see that concern as a whole, and must love it. "Without passion," said Lord Haldane to the students of Edinburgh University, "nothing great is, or ever has been, accomplished."[10]

Lord Haldane went on to compare the statesman with the expert, greatly to the latter's disadvantage. Much that has happened lately would probably cause Lord Haldane to express himself differently now. In any case we shall not follow him here. We shall instead place the expert in the same class as the industrial statesman because the former requires an equally high degree of skill in thinking and at least as complex (if not so widely varied or so emotional) an interest as the latter. The industrial statesman may be compared to the astronomer who uses the telescope to increase his grasp of the whole, while the expert rather resembles the naturalist whose microscope enables him to see the parts in great detail. It is evident that the successful development of industry demands not only the expert in special branches of science or technology, but also the industrial statesman who co-ordinates the work of experts in different fields, and who is himself enough of a specialist fully to understand his experts, to command their confidence, and, when necessary, to decide between them. Whoever has authority must also have knowledge.

The members of class B require fewer associations to connect the ideas which constitute their single wide interests. They need less skill in thinking than members of class A. They require, on the other hand, a very wide descriptive knowledge of material

7 "Evolution of Educational Theory," p. 225.
8 "Principles of Psychology," vol. ii., p. 424.

9 "The Great Society," p. 87.
10 "The Conduct of Life," p. 25.

things, and as much of this knowledge as possible they should have acquired at first hand from direct sense impressions. Last, but by no means least, the works manager and his immediate assistants need to interest themselves in the social and economic welfare—including the further education, recreation, and housing—of all their employees, and this interest will help to form the nucleus of those single wide interests which are to include all the activities of members of class B.

Foremen and leading hands have hitherto been generally recruited from among skilled tradesmen. They are therefore presumed to be qualified themselves to perform every task they have to supervise, and even to perform it better than the men who are actually doing the work. Upon this presumption is based the claim that the shop foreman must be paid a higher wage than any workman under him. This view, accepted as it generally is by employers and employed alike, is responsible for no small restriction of output. But it is based on a misconception, since the foreman is paid for supervising men, and the workman for manipulating material—two quite incommensurate processes. There are, however, signs of change. Technically trained foremen whose wages may (to start with) be much less than those of the men they have to look after, are already being employed, especially in shops where much repetition work is done. Yet it remains true that the qualities now most sought for in foremen and leading hands are those of the craftsman whose interest is centred in his manual work.

The operative skilled tradesman whom, for this reason, we have placed in the same class as his foreman is distinguished from the machine man in class D in that the operative in class C has a *variety* of skilled work to do, while the members of class D who may do skilled work, *repeat* the same process over and over again until its performance is governed by habit, so that it almost ceases to receive attention. On the one hand, ideas connected with *doing*, like ideas associated with a strong instinct, are peculiarly liable to receive attention, so that the work of the skilled tradesman in class C is well able to form a strong centre for his single wide interest. On the other hand, ideas connected with the repetition work of class D tend to become circumscribed and cut off from other interests. There is, however, reason to believe that repetition work is not altogether uninteresting to a certain type of mind. It is, indeed, actually preferred by some people, including many women. Such work may, therefore, form a substantial, if not a dominant, part of an interest that is not rich in exciting ideas. The remaining part of the single wide interest is of special importance in the case of class D. When an eight-hours day is universal it may be that the artisan or labourer who leaves work with much of his day still before him and feeling pleasantly exercised rather than unduly tired by his somewhat monotonous but by no means exacting labour, will devote himself increasingly to national and municipal affairs. With that end in view we must see to it that the average member of class D receives —not only in maturity through the Workers' Educational Association, but also in youth through vocational part-time classes—the kind of training which shall best develop a single interest, wide enough to include the highest ideals of patriotism as well as loyalty to a particular industrial class.

IV.

We have next to consider how to develop in a sufficient number of suitably selected persons the qualities which we have indicated as specially needed in each class of industrial occupation.

Childhood up to, say, twelve years of age has few organised interests. Accordingly, the need for a coherent curriculum, aiming at developing a single wide interest, does not obtrude itself until adolescence begins. The future member of classes A and B will normally spend much of his adolescence in a secondary school. Of these schools it is convenient to distinguish two types, named "Higher" and "Lower" respectively in the accompanying diagram.

The chief function of the secondary school, the school for adolescents, is to foster the growth of true religion—"not theology nor yet ethics, but personal and experimenetal"[11]—and around this centre to build up, out of the miscellaneous information obtained in childhood and the coherent curriculum which the secondary school should itself provide, the beginnings of that single wide interest which should continue to grow throughout maturity. The skill in thinking which the secondary school must also cultivate is best practised upon a number of closely associated ideas—a coherent interest—because, unless the idea before consciousness at any moment calls up *many* others, from which the will can select that which is next to receive attention, this faculty cannot be practised; and without practice skill in thinking cannot be developed.

The broad foundation metaphor, of which Dr. Kerschensteiner[12] has made such fine fun, is probably responsible for the fact that most secondary schools aim in theory, and some lower secondary schools (unfortunately) in practice also, at comprehensiveness rather than at coherence of interest: they have failed to realise that coherence at seventeen is the surest way to comprehensiveness at twenty-seven. Concentration has, however, been practised by the classical sides of English public schools. But in many of the newer secondary schools six or seven distinct subjects are taught out of all relation to one another by as many separate specialists, and the form master himself is almost unknown!

The future member of class A should remain at his higher secondary school and enter the university at, or soon after, the age of eighteen. It is true that the future engineer often spends some time in works between school and college; but there is a growing consensus of opinion that this period should not be too long. Perhaps from Christmas until the following October would be ideal if both school-leaving and university-entrance scholarships could be awarded, as those of some Oxford and Cambridge colleges already are, just before Christmas.

It is to the university that we shall principally look in the future for an essential part of the specific training of members of class A, for the men with creative minds, inventors of new appliances and processes, men who shall not merely be able to follow existing practice but also to cope with new problems and even to lead in new lines of advance. And our university courses, if they succeed in producing men of this type, will do so, not because of the knowledge they impart, wide though it be, but because of the stress they lay on the acquisition of skill in thinking along with knowledge. It is skill in thinking—skill in applying old knowledge to new situations—rather than knowledge itself without such skill, that now, as always, marks the really practical man. If, in fact, his university course can, in Huxley's phrase, give him "real, precise, thorough, and practical knowledge of fundamentals," the candidate for membership of class A may well wait for subsequent works experience, post-graduate evening classes, and private reading, to develop further his *technical* information to a marketable standard. Whatever letters he may

11 G. Stanley Hall, "Adolescence," vol. ii., p. 326.
12 "Schools and the Nation," p. 275.

be able to write after his name, his undergraduate course should have aimed at making him a bachelor of arts, skilled in the art of learning, and only incidentally have given him a body of scientific knowledge capable of immediate application.

This view of the chief aim of a university course insists that there shall not be overmuch lecturing; that information shall be acquired because it is immediately and urgently needed for the solution of some practical problem; that a larger proportion of the most able students shall remain "up" after taking their degrees for the purpose of undertaking original course must be at all detached from practical things. It is no more possible to develop skill in thinking without knowledge than to acquire skill in the use of tools without material to work upon. Technical knowledge is, in fact, a most excellent foundation and medium for cultivating skill in thinking.

England is fortunate in that most of her highest study and research in technology form part of the work of her universities. For a university is more than a university course or an aggregate of such courses. The opportunities which a university affords for studying elective

The intercept made on any ordinate by the enclosed area which corresponds to any course varies with (but not strictly in proportion to) the number of students of the corresponding age who should be following the course in question.

—>>> / —>> / —> indicates that the great majority of the / a constant supply of systematically selected / a few exceptional persons leaving the course which corresponds to the area in which the arrow-head lies should proceed to the course towards which it points.

The unshaded portion of the diagram is concerned with "full-time" education; that is, with schools and classes meeting in the daytime and occupying all the working hours of those by whom they are attended. The central singly shaded area relates to part-time classes: classes meeting either in the day or in the evening, and intended for persons whose employment occupies the greater part of their time. The doubly shaded region on the right of the diagram corresponds to those later years of industrial practice when a man has ceased to attend organised courses of study bearing upon his trade or profession.

research; and that, while the most distinguished professors shall take part in the teaching of the undergraduates from the outset, they shall do so, not because of the knowledge they are peculiarly able to impart, but because "the personal influence of the man doing original work in his subject inspires belief in it, awakens enthusiasm, and gains disciples."[13]

In urging that the chief aim of a university course must be to cultivate skill in thinking rather than to impart information, we do not mean that such a subjects are important. But far more important is the intimate and constant association in the various students' societies, as well as in the lecture rooms, drawing offices, or laboratories, between students in different faculties, from different countries, and with entirely different outlooks.[14]

But the State cannot afford to provide a university training for all its citizens. The majority, even of class B, will be compelled by economic pressure to begin earning money before they are twenty years

[13] Final Report of the Royal Commission on University Education in London, p. 29.

[14] See Newman's eloquent words quoted by the Royal Commission on University Education in London (*loc. cit.*, pp. 26, 27).

old. Where a suitable senior technical school exists, they will do well to receive in it the specific training which should occupy the last two years before their entry into industrial life. The very important place which a senior technical school should fill in the educational system of an industrial district is, as yet, hardly realised.

The future member of class C should be transferred from the public elementary school to the junior technical school when other children are transferred to the lower secondary school. The junior technical school should prepare him for entering one of a group of allied trades at or about the age of fifteen. It is not, however, the function of the junior technical school to teach him a trade, but rather to develop his manual skill in work that is closely related to that of the trade to which he is looking forward, and to extend the great interest which he cannot help feeling in such work so as also to include so-called "general" subjects. Experience has shown that he will thus make more progress in these "general" subjects than if he were studying them in a school which has no specific aim.

When the future members of classes A, B, and C have been transferred from the public elementary schools at the age of twelve, the work of the future members of class D who are left behind should differ[15] somewhat from the general work done by all children below the age of twelve. It might well be centred in (but not, of course, be confined to) handwork during these last two years, and so have much in common with the training of Boy Scouts.

Even when the last two years of whole-time education have been admirably adapted to prepare the educand for his imminent vocation, some educational discontinuity must always occur as he leaves whole-time school or college to continue his education in industrial life. Part-time classes afford the best means of reducing this discontinuity to a minimum. Accordingly, every boy or man, as he first enters upon industrial work, should attend suitable part-time classes. No feature of English education is more striking to the foreign observer than the system of part-time courses in all our great centres of industry. At the present time most part-time courses involve attendance on three evenings a week for several successive years. Although they cannot cover the whole ground of university courses, they aim (for the most part) at affording an alternative means of training men to occupy positions of responsibility in industrial affairs.

While, however, our part-time classes are thus training technical men, they are neglecting manual workers. Instead of attending these technical classes, the boy who enters works at fourteen or fifteen years of age requires (at least until he is seventeen years old) a special type of part-time course, to which the name "minor course" has lately been given. One of the principal objects of such a course is to provide instruction in those matters which the trade apprentice in bygone days learned by close association with a master craftsman, and which are commonly lost to him under modern industrial conditions. The minor course will therefore "have as its central subject the trade processes or craft in which the students are engaged."[16] But so-called "citizenship" subjects—such as history and economics, the study of which will make for a better understanding of problems concerning wages and hours of labour—also form an essential part of a minor course. It remains to add that the need for minor courses is not yet sufficiently appreciated, with the result that a great opportunity of educating during the critical years of adolescence the numerous members of class C and class D is being neglected.

15 The difference is marked by the dotted line at y in the diagram.
16 Board of Education Circular 894.

V.

The system of education, the outline of which I have thus described, is represented on paper in the diagram. Its realisation in any English industrial district—say, Manchester—would need some, but not much, co-ordination; for the diagram represents neither what is nor what might be under ideal conditions, but what could be made out of what is with the maximum of advantage in proportion to the effort spent in making the change. The co-operation of local education authorities, universities, the Government, employers, and parents would be required in order to complete this change.

But already there are signs that all the necessary co-operation is forthcoming. Many striking instances might be cited in support of this statement did time permit. I must, however, be content to mention only two: Mr. Henderson's new scheme for the organisation and development of industrial research, and a similar scheme recently prepared by a committee of the Manchester Engineers' Club. This latter scheme provides for organised co-operation between schools, colleges, and engineering firms in the education of engineers and for the encouragement of research in the following, among other ways:—

> By developing co-operation between engineering firms on the one hand and universities and technical colleges on the other, so as to establish such "schools of thought" as exist in the research departments of great Continental and American engineering firms, but cannot be fostered in the comparatively small establishments (and smaller research departments) of most British engineering firms.

VI.

The co-ordinated system of schools, colleges, and works represented in the diagram will not be satisfactory unless it is thoroughly democratic. It is true that innate differences between individuals cannot well be distinguished from differences produced by home surroundings. But whoever is best fitted by nature and nurture for any particular class of occupation should be selected to receive, if necessary at the State's expense, the training which will best prepare him for it. Education authorities should see that the number of persons so selected is sufficient—but not much more than sufficient—to supply whatever demand is also a need.

VII.

At present the supply of men for the highest classes of work falls very far short of the demand. Every year the number of appointments offered to School of Technology graduates greatly exceeds the number of these graduates. Not only is this true of posts in chemical works, but also of electrical and other engineering appointments. Although the number of undergraduates in the School of Technology (Faculty of Technology in Manchester University) increased by 50 per cent. in the two years before the war, the demand for their services after graduation increased in a still larger proportion.

Such facts need to be realised by boys and by their parents. But it is even more important that they should realise that the highest kind of technological work is noble work, worthy of a lifetime's duration. The profession of applying science to industry is rich in opportunities for helping to bring about the ideal

future of the human race. While it is the glory of the medical profession, for example, that it assists in preventing a wastage of life that could not but retard human progress, we must remember that technology helps to produce what medicine and surgery help to preserve. The great increase in population which began in the middle of the eighteenth century was directly due to mechanical invention. Indeed, the application of science to industry not only renders possible a rapid growth of population, but it exempts an ever-growing proportion of this increasing population from the need for incessant physical toil. Moreover, all that acceleration of human progress which results from the increasing national expenditure on the education of the people would cease with any interruption of the march of technological invention.

Every improvement, then, which the technologist may be able to make in the direction of cheapening production—reducing, for example, the cost of a brake horse-power hour—will help to increase the number of men whom the community can spare for the study of classical literature in order to keep the thought of our time in touch with the best of the thought of ancient Greece and Rome; it will help to increase, too, the number of those who can be spared by this generation to devote their lives to scientific research, to widen the scope of human thought, to teach men more of the works and ways of God, and to obtain the knowledge which technologists of the future will apply for the benefit of generations not yet born; and, most important of all, it will help to support the seers and the prophets on whom we so largely depend in the weightiest affairs of human life.

THE BRITISH ASSOCIATION.

SECTION M.

AGRICULTURE.

OPENING ADDRESS BY R. H. REW,[1] C.B., PRESIDENT OF THE SECTION.

Farming and Food Supplies in Time of War.

BEFORE considering the position of farming in the present war, we may briefly glance at its position when a century ago the nation was similarly engaged in a vital struggle.

From February, 1793, until 1815, with two brief intervals, we were at war, and the conflict embraced not only practically all Europe but America as well. The latter half of the eighteenth century had witnessed a revolution of British agriculture. The work of Jethro Tull, "Turnip" Townshend, Robert Bakewell, and their disciples, had established the principles of modern farming. Coke of Holkham had begun his missionary work; Arthur Young was preaching the gospel of progress; and in 1803 Humphry Davy delivered his epoch-making lectures on agricultural chemistry. Common-field cultivation, with all its hindrances to progress, was rapidly being extinguished, accelerated by the General Inclosure Act of 1801. A general idea of the state of agriculture may be obtained from the estimates made by W. T. Comber of the area in England and Wales under different crops in 1808. There were then no official returns, which, indeed, were not started until 1866; but these estimates have been generally accepted as approximately accurate, and are at any rate the nearest approach we have to definite information.

I give for comparison the figures from the agricultural returns of 1914, which approximately correspond to those of the earlier date:—

	1808 Acres	1914 Acres
Wheat	3,160,000	1,807,498
Barley and rye	861,000	1,558,670
Oats and beans	2,872,000	2,223,642
Clover, rye-grass, etc.	1,149,000	2,558,735
Roots and cabbages cultivated by the plough...	1,150,000	2,077,487
Fallow	2,297,000	340,737
Hop grounds	36,000	36,661
Land depastured by cattle ...	17,479,000	16,115,750

The returns in 1914 comprise a larger variety of crops than were cultivated in 1808. Potatoes, for instance, were then only just beginning to be grown as a field-crop, and I have included them, together with Kohl-rabi and rape, among "roots and cabbages."

The population of England and Wales in 1801 was 8,892,536, so that there were 35½ acres under wheat for every hundred inhabitants. In 1914 the population was 37,302,983, and for every hundred inhabitants there were 5 acres under wheat.

The yield of wheat during the twenty years ending 1795 was estimated at 3 qr. per acre[2]; in 1914 it was 4 qr. per acre. The quantity of home-grown wheat per head of population was therefore 8½ bushels in 1808, and 1½ bushels in 1914. Nevertheless, even at that time, the country was not self-supporting in breadstuffs. In 1810, 1,305,000 qr. of wheat and 473,000 cwt. of flour were imported. The average annual imports of wheat from 1801 to 1810 were 601,000 qr., and from 1811 to 1820 458,000 qr. Up to the last decade of the eighteenth century England was an exporting rather than an importing country, and bounties on exports were offered when prices were low, from 1689 to 1814, though none were, in fact, paid after 1792.

During the war period we are considering, the annual average price of wheat ranged from 49*s.* 3*d.* per qr. in 1793 to 126*s.* 6*d.* per qr. in 1812; the real price in the latter year, owing to the depreciation of the currency, being not more than 100*s.* In 1814 the nominal price was 74*s.* 4*d.* and the real price not more than 54*s.* per qr.[3] The extent to which these high and widely varying prices were affected by the European war has been the subject of controversy. As we mainly depended on the Continent for any addition to our own resources, the diminished production during the earlier years in the Netherlands, Germany, and Italy, and in the later years of the war in Russia, Poland, Prussia, Saxony, and the Peninsula, reduced possible supplies. At the same time the rates of freight and insurance, especially in the later years of the war, increased very considerably. Tooke mentions a freight of 30*l.* per ton on hemp from St. Petersburg in 1809. On the other hand, a powerful impetus was given to home production, which was stimulated by Government action and private enterprise. Inclosure was encouraged by the General Inclosure Act of 1801, and 1934 Inclosure Acts were passed from 1793 to 1815. The schemes for increasing and conserving food supplies were various. The Board of Agriculture, for example, offered prizes of 50, 30, and 20 guineas respectively to the persons who in the spring of 1805 cultivated the greatest number of acres—not fewer than 20—of spring wheat.[4] In 1795 a Select Committee recommended that bounties should be granted to encourage the cultivation of potatoes on

1 Slightly abridged by the author.

4 "Annals of Agriculture," 1805.

"lands at present lying waste, uncultivated, or unproductive," and that means should at once be adopted to add at least 150,000 and perhaps 300,000 acres to the land under cultivation "as the only effectual means of preventing that importation of corn, and disadvantages therefrom, by which this country has already so deeply suffered."

The main cause of high prices and scarcity was the failure of the harvests. Mr. Prothero thus analyses the wheat harvests of the twenty-two years 1793–1814: "Fourteen were deficient; in seven out of the fourteen the crops failed to a remarkable extent, namely, in 1795, 1799, 1800, 1809, 1810, 1811, 1812. Six produced an average yield. Only two, 1796 and 1813, were abundant; but the latter was long regarded as the best within living memory."[5]

It appears paradoxical, but in a sense it is true, to say that the scarcity of wheat in certain years arose from the fact that the country was too largely dependent on its own crop. The risk of a bad harvest in a climate such as that of the British Isles must always be serious, and by the fortune of war this risk between 1793 and 1814 turned out to be very high. When supplies are drawn from the four quarters of the globe, it is evident that the risk of a shortage in time of peace is greatly reduced. Whether in a great war it is preferable to be more dependent on the sea than on the season is debatable.

In comparison with wars for national existence, such as that against Napoleon, and in a still sterner sense that in which we are now engaged, other conflicts appear insignificant. The Crimean War, however, did affect our food supplies and had a reflex action on British agriculture. The cessation of imports from Russia caused a rise in the price of corn. The average price of wheat rose to 72*s*. 5*d*. per qr. in 1854, 74*s*. 8*d*. in 1855, and 69*s*. 2*d*. in 1856. Only once before (in 1839) during the previous thirty-five years had it risen above 70*s*. There were then no agricultural returns, but the estimates of Lawes, which were generally accepted, put the area under wheat at a little more than 4,000,000 acres, a higher figure than has been suggested for any other period. It is, indeed, highly probable that the Crimean War marked the maximum of wheat cultivation in this country. It was a time of great agricultural activity and of rapid progress. To their astonishment, farmers had found, after an interval of panic, that the Repeal of the Corn Laws had not obliterated British agriculture, and that even the price of wheat was not invariably lower than it had often been before 1846. Caird had preached "High Farming" in 1848 and found many disciples, capital was poured into the land, and the high prices of the Crimean period stimulated enterprise and restored confidence in agriculture.

To generalise very roughly, it may be said that while the Napoleonic wars were followed by the deepest depression in agriculture, the Crimean War was followed by a heyday of agricultural prosperity which lasted for more than twenty years. What the agricultural sequel to the present war may be, I leave to others to estimate, and I turn to consider briefly some of its effects on British farming up to the present time.

Harvest had just begun when war broke out on August 4; indeed, in the earlier districts a good deal of corn was already cut. The harvest of 1914 was, in fact, with the exception of that of 1911, the earliest of recent years, as it was also one of the most quickly gathered. The agricultural situation may perhaps be concisely shown by giving the returns of the crops then in hand, *i.e.* in course of gathering or in the ground, with the numbers of live stock as returned on farms in the previous June. The figures are for the United Kingdom, and I add the average for the preceding ten years for comparison:—

	1914	Average 1904–13
	Qr.	Qr.
Wheat	7,804,000	7,094,000
Barley	8,066,000	7,965,000
Oats	20,664,000	21,564,000
Beans	1,120,000	1,059,000
Peas	374,000	525,000
	Tons	Tons
Potatoes	7,476,000	6,592,000
Turnips and swedes ...	24,196,000	26,901,000
Mangold	9,522,000	9,934,000
Hay	12,403,000	14,148,000
	Cwt.	Cwt.
Hops	507,000	354,000
	No.	No.
Cattle	12,185,000	11,756,000
Sheep	27,964,000	29,882,000
Pigs	3,953,000	3,805,000
Horses	1,851,000	2,059,000

Farmers had thus rather more than their usual supplies of nearly every crop, the chief deficiencies being in peas, roots, and hay. The shortage of the hay crop was, however, in some measure made up by the large stocks left from the unusually heavy crop of 1913. It was fortunate from the food-supply point of view that two of the most plentiful crops were wheat and potatoes. The head of cattle was very satisfactory, being the largest on record, and pigs were well above average. Sheep, always apt to fluctuate in numbers, were much below average, the total being the smallest since 1882 with the exception of 1913.

On the whole, it was a good year agriculturally, and the supply of home-grown produce at the beginning of the war was bountiful. Nature at any rate had provided for us more generously than we had a right to expect.

At first it appeared as if farmers were likely to be sufferers rather than gainers by the war. Prices of feeding-stuffs, especially linseed and cotton-cakes, maize-meal, rice-meal, and barley-meal, rose at once, recruiting affected the labour supply, and difficulties arose in the distribution of produce by rail. With one or two exceptions, such as oats, the prices of farm produce showed but little rise for three or four months after the war began. Wheat rose about 10 per cent., barley remained about normal, cattle by November had not risen more than 3 per cent., sheep and veal-calves showed no rise until December, while poultry was actually cheaper than usual, though eggs rose considerably. Butter rose slightly, and cheese remained about normal. Up to nearly the end of the year, in fact, it may be said generally that British farm-produce made very little more money than usual.

Meanwhile, the nation began to take a keen interest in the agricultural resources of the country, and farming became the object of general solicitude. We started with great energy to improvise, in truly British fashion, the means of facing the supreme crisis of our fate, but the elementary fact at once became obvious that it is impossible to improvise food. The main farm-crops take an unreasonably long time to grow, even if the land is prepared for them, and a sudden extension of the area under cultivation is not a simple proposition. It was freely pointed out—with undeniable truth—that our agricultural system had not been arranged to meet the conditions of a great European war, and many suggestions were made to meet the emergency. Some of these suggestions involved intervention by legislative or administrative action. It was decided that any attempt violently to

5 "English Farming, Past and Present," p. 269.

divert the course of farming from its normal channels would probably not result in an increased total production from the land. The Agricultural Consultative Committee, appointed by the President of the Board of Agriculture on August 10, issued some excellent advice to farmers as to their general line of policy and the best means by which they could serve the nation, and this was supplemented by the Board and by the agricultural colleges and local organisations throughout the country. No fewer than thirty special leaflets were issued by the Board, but, while it may, I think, fairly be claimed that all the recommendations made officially were sound and reasonable, I should be the last to aver that farmers were universally guided by them. They do not accept official action effusively:—

> Unkempt about those hedges blows
> An English unofficial rose,

and official plants do not flourish naturally in farm hedgerows. It was, however, fairly evident that patriotism would suggest an effort to obtain the maximum production from the land, and there were good reasons to think that self-interest would indicate the same course. It must be admitted, however, that during the autumn the lure of self-interest was not very apparent. Food-prices, however, at the end of the year began to rise rapidly. English wheat in December was 25 per cent. above the July level, in January 45 per cent., in February and March 60 per cent., and in May 80 per cent. Imported wheat generally rose to a still greater extent, prices in May standing for No. 2 North Manitoba 95 per cent., and No. 2 Hard Winter 90 per cent. above July level. The greater rise in imported wheat may be noted as vindicating farmers against the charge which was made against them of unreasonably withholding their wheat from the market. Cattle and sheep rose more slowly, but in March prices of both had risen by 20 per cent., and in May and June cattle had risen by about 40 per cent. Butter rose by about 20 per cent., and cheese by about 40 per cent. Milk rose little through the winter, but when summer contracts were made prices remained generally at the winter level.

British agriculture, like the British Isles, is a comparatively small affair geographically. The 47 million acres which it occupies, compared with the 80 million acres of Germany or the 90 million acres of France, and still more the 290 million acres of the United States, represent an area which may be termed manageable, and about which one might expect to generalise without much difficulty. But, in fact, generalisation is impossible. Even on the 27 million acres of farm land in England and Wales there is probably more diversity to the square mile than in any country on earth. The variations in local conditions, class of farming, and status of occupier preclude the possibility of making any general statement without elaborate qualifications. Thus whatever one might say as to the effects of the war on agriculture would be certain to be inaccurate in some districts and as regards some farmers.

There are three main agricultural groups, corn-growing, grazing, and dairying. They overlap and intermingle indefinitely, and there are other important groups, such as fruit-growing, vegetable-growing, hop-growing, etc., which represent a very large share of the enterprise and capital engaged on the land. The receipts of the corn-growing farmer, generally speaking, were substantially increased. Probably about 50 per cent. of the wheat-crop had been sold before prices rose above 40s. per quarter, and there was very little left on the farms when they reached their maximum in May. Oats rose rather more quickly, but did not reach so high a level, relatively, as wheat. Barley—owing perhaps to enforced and voluntary temperance—never made exceptional prices, and, in fact, the best malting barleys were of rather less than average value. There is no doubt, however, that farmers who depended mainly on corn-growing found an exceptionally good market for their crops and made substantial profits. Farmers who depended mainly on stock were less generally fortunate, although stock were at a fairly high level of price when the war began. Sheep for some time showed no signs of getting dearer, but in the spring prices rose substantially, and a good demand for wool—which in one or two cases touched 2s. per lb.—made the flockmasters' returns on the whole very satisfactory. Cattle followed much the same course; stores were dear, but by the time fat stock came out of the yards or off the grass prices had risen to a very remunerative level. The large demands on imported supplies of meat for the British and French armies occasioned a distinct shortage for the civil population, but this was relieved by a reduced demand, so that the effect upon prices of native beef and mutton was not so great as might have been expected. The influence of a rise of price upon demand is more marked in the case of meat than in that of bread. While there has been a distinct reduction in the consumption of meat, there is no evidence of a reduced consumption of bread.

Dairy farmers generally found themselves in difficulties. Prices of butter and cheese increased but slightly, and milk remained for a considerable period almost unchanged. The rise in the prices of feeding-stuffs and the loss of milkers aggravated their troubles. An actual instance of the position in February as affecting a fairly typical two-hundred acre farm may be quoted. It had thirty milch cows producing about 16,500 gallons per annum. The cake bill showed an advance of 50 per cent., and wages had risen 12 per cent. It was calculated that the extra cost was 1·3*d.* per gallon of milk. Later the prices of milk, butter, and cheese rose, but on the whole it cannot be said that dairy farmers generally made exceptional profits.

While it is certain that the gross receipts by farmers were substantially increased, it is very difficult to estimate what the net pecuniary gain to agriculture has been. It can only be said generally that while some have made substantial profits, which were probably in very few cases excessive, many others have on balance (after allowing for extra cost) done no better financially, and some perhaps even worse, than in an average year of peace. With regard to one item of extra cost, that of labour, it is possible to make an approximate estimate. Agricultural labourers were among the first to respond to the call for the new armies, and, up to the end of January, 15 per cent. had joined the forces of the Crown. This considerable depletion of labour was not acutely felt by farmers during the winter, but during the spring and summer serious difficulty was experienced and many devices were suggested—some of which were adopted—for meeting it. Naturally the wages of those agricultural labourers who were left rose, the rise varying in different districts but being generally from 1*s.* 6*d.* to 3*s.* per week. Owing to the rise in the price of commodities, this increase of wages cannot be regarded as a profit to the labourers, but it is, of course, an outlay by farmers, which in England and Wales may be reckoned as amounting to an aggregate of about 2,000,000*l.*

This country has never suffered from a dearth of agricultural advisers, and in such a time as the present, when everyone is anxious to help the country, it is natural that they should be unusually plentiful. Advice was freely offered both to the Government how to deal with farmers and to farmers how to deal with

the land. Whether in consequence of advice or in spite of it, it may fairly be said that farmers throughout the United Kingdom have done their duty. They have met their difficulties doggedly, and have shown an appreciation of the situation which does credit to their intelligence. It was not easy last autumn when farmers had to lay their plans for the agricultural year to forecast the future. We were all optimists then, and many thought that the war might be over before the crops then being planted were reaped. It was clear, however, that the national interest lay in maintaining and, so far as possible, increasing the produce of the land. In the quiet, determined way which is characteristic of them, farmers devoted themselves to the task, and the returns recently issued give the measure of their achievement. They have added 22 per cent. to the acreage of wheat and 7 per cent. to the acreage of oats, and they have kept the area of potatoes up to the high and sufficient level of the previous year. These are the three most important crops. They have also not only maintained the stock of cattle, which was the largest on record, but, in spite of unfavourable conditions and a bad lambing season, they have increased the stock of sheep. In view of these facts, I venture to say that British and Irish farmers have shown both patriotism and intelligence, and may fairly claim to have contributed their share to the national effort.

The share of British agriculture in the food supply of the nation is more considerable than is sometimes realised. When I last had the honour to address the British Association I ventured to emphasise this point, and I may be allowed to repeat, in a somewhat different form and for a later period, the figures then given. Taking those articles of food which are more or less produced at home, the respective proportions contributed by the United Kingdom, the rest of the Empire, and foreign countries were on the average of the five years 1910–14 as follows:—

—	United Kingdom	British Empire overseas	Foreign countries
	Per cent.	Per cent.	Per cent.
Wheat	19·0	39·3	41·7
Meat	57·9	10·7	31·4
Poultry	82·7	0·2	17·1
Eggs	67·6	0·1	32·3
Butter (including margarine)	25·1	13·3	61·6
Cheese	19·5	65·4	15·1
Milk (including cream) ...	95·4	0·0	4·6
Fruit	36·3	8·3	55·4
Vegetables	91·8	1·1	7·1

The war has directly affected some of our food supplies by interposing barriers against the exports of certain countries. Fortunately we were in no way dependent for any of these foods upon our enemies, though Germany was one of our main sources of supply for sugar. We received some small quantities of wheat or flour and of eggs from Germany, Hungary, and Turkey, some poultry from Austria-Hungary, and some fruit from Germany and Turkey, but the whole amount was insignificant. The practical cessation of supplies from Russia was the most serious loss, as we drew from thence on an average 9 per cent. of our wheat, 9 per cent. of our butter, and 16 per cent. of our eggs.

Within the first few days of the war, the Government, through the Board of Agriculture, obtained returns not only of the stocks of all kinds of foodstuffs in the country, but also of the stocks of feeding-stuffs for animals and of fertilisers for the land. Powers were taken under the Articles of Commerce (Returns, etc.) Act to compel holders of stocks to make returns, but it is due to the trading community to say that in only two instances, so far the Board of Agriculture was concerned, was it necessary to have recourse to compulsion. The returns of stocks of food-stuffs, feeding-stuffs, and fertilisers have been made regularly to the Board of Agriculture[6] every month since the outbreak of war, and the loyal co-operation of the traders concerned deserves cordial recognition by those whose official duty has been rendered comparatively easy by their assistance.

A very casual glance at the national dietary suffices to show that John Bull is an omnivorous feeder, and as the whole world has eagerly catered for his table his demands are exigent. But, for various reasons, our daily bread, reluctant though most of us would be to be restricted to it, is regarded as the measure and index of our food supplies. On August 4 the Board of Agriculture published an announcement that they estimated the wheat-crop then on the verge of harvest at 7,000,000 quarters, and that, including other stocks in hand, there was at that time sufficient wheat in the country to feed the whole population for four months; and a few days later, having then obtained further information from about 160 of the principal millers, they stated that the supplies in the country were sufficient for five months' consumption. The Board also announced, on August 5, that the potato crop would furnish a full supply for a whole year's consumption without the necessity for any addition from imports. When it was further announced that the Government had taken steps to ensure against a shortage of sugar it began to be generally realised that at any rate the country was not in imminent danger of starvation. Indeed, on a broad survey of the whole situation, it was apparent that our native resources, together with the accumulated stocks of various commodities held in granaries, warehouses, and cold stores, would enable the United Kingdom to face even the unimaginable contingency of a complete blockade of all its ports for a considerable period.

In these circumstances it appeared that, provided adequate protection were given against unusual risks, commercial enterprise might in the main be relied upon to supply the demands of the people in the normal manner and in the usual course of business. It is a self-evident axiom that it is better not to interfere in business matters unless there is a paramount necessity for interference.

The machinery of modern business in a highly organised community is very complicated; the innumerable cog-wheels are hidden while the machine is running normally, but every single one of these becomes very obvious when you attempt to introduce a crowbar. With one or two exceptions the purveyors of food to the nation were left to conduct their business without official interference, though the Board of Trade took steps to ascertain what were the retail prices justified by the wholesale conditions and to disseminate the information for the protection of consumers against unreasonable charges.

One measure of a drastic and widespread nature was adopted. The exportation of a large number of commodities was prohibited. This was done for two reasons: (1) to conserve stocks in this country, and (2) to prevent goods from reaching the enemy. The latter object could be attained only very partially by this method so long as any sources of supply other than the ports of the United Kingdom were open to the enemy or to adjoining neutral countries. The former object—with which we are now only concerned—was on the whole achieved. The Board of Agriculture, concerned for the maintenance of our flocks and herds, at once secured a general prohibition of the exportation

6 Returns in Scotland and Ireland are made to the Agricultural Departments of those countries and the results transmitted to the Board of Agriculture and Fisheries.

of all kinds of feeding-stuffs for animals. Many kinds of food-stuffs were at once included, and later additions were made, so that for a long time past nearly all kinds of food have been included, though in some cases the prohibition does not apply to the British Empire or to our Allies. The exportation of fertilisers, agricultural seeds, binder twine, and certain other commodities more or less directly connected with the conservation of our food supplies, was also prohibited, so that generally it may be said that the outlet for any food in the country was under effective control. This is not the time or place to discuss the reasons why in some instances limited quantities of certain articles were allowed to escape under licence. It is only necessary to remark that in all such cases there were cogent reasons in the national interest for the action taken.

Direct Government intervention in regard to food supplies was limited to three commodities—sugar, meat, and wheat. In the case of sugar the whole business of supply was taken over by the Government—a huge undertaking, but administratively a comparatively simple one, owing to the fact that there are no home-grown supplies. Intervention in the meat trade was necessitated by the fact that the enormous demands of the Allied armies had to be met by drafts upon one particular kind of meat and mainly from one particular source. The Board of Trade co-operated with the War Office, and a scheme was evolved whereby a very large part of the output of meat from South America and Australia comes under Government control.

As regards wheat, the intervention of the Government took two forms. The scheme whereby the importation of wheat from India was undertaken by the British Government, in co-operation with the Indian Government, arose primarily from conditions in India rather than from conditions in the United Kingdom, although it is hoped and believed that the results will prove to be mutually advantageous. Other than this the intervention of the Government in regard to wheat was devised as an insurance against the risk of interruption of normal supplies, its main object being to prevent the stocks of wheat in the country from falling to a dangerous level at a time when the home crop would be practically exhausted. When the home crop is just harvested there are ample reserves in the country for some months, and, as the United States and Canada are at the same time selling freely, stocks held by the trade are usually high. While home-grown wheat remains on the farms it is practically an additional reserve supplementary to the commercial reserves. When it leaves the farmer's hands, even although it may not actually go into consumption, it becomes part of the commercial reserve. This reserve in the nature of business tends to be constant, but fluctuates within rather wide limits under the influence of market conditions. If the price of wheat rises substantially and the capital represented by a given quantity increases, there is a natural tendency to reduce stocks. If also there is any indication of a falling market ahead, whether from favourable crop prospects or the release of supplies now held off the market for any reason, a prudent trader reduces his stocks to the smallest quantity on which he can keep his business running. So long as shipments reach this country, as in normal times they do, with, as a member of the Baltic once expressed it to me, "the regularity of 'buses running down Cheapside," the country may safely rely on receiving its daily bread automatically. But if any interruption occurred at a time when the trade, for the reasons just indicated, happened to be running on low stocks, the margin for contingencies might be insufficient. I am, of course, debarred from discussing the method adopted or the manner in which the scheme was carried out, but, as the cereal year for which it was devised is over, it is permissible to state that the object in view was successfully achieved.

Of the 47,000,000 people who form the population of the United Kingdom the large majority are absolutely dependent for their daily food on the organisation and regular distribution of supplies. The countryman, even if he possesses no more than a pig and a garden, might exist for a short time, but the town-dweller would speedily starve if the organisation of supplies broke down. He does not, perhaps, sufficiently realise the intricacy of the commercial arrangements which make up that organisation, or the obstacles which arise when the whole economic basis of the community is disturbed by a cataclysm such as that which came upon us thirteen months ago. The sorry catchword, "Business as usual," must have sounded very ironically in the ears of many business men confronted with unforeseen and unprecedented difficulties on every side. The indomitable spirit with which they were met, the energy and determination with which they were overcome, afford further evidence of that which has been so gloriously demonstrated on land and sea, that the traditional courage and grit of the British race have not been lost.

To the question how have our oversea food supplies been maintained during the first year of the war, the best answer can be given in figures.

Imports of the principal kinds of food during the first twelve months of the war were as under, the figures for the corresponding period of 1913–14 being shown for comparison:—

	1914–15 Thousands of cwt.	1913–14 Thousands of cwt.	Increase + or Decrease − per cent.
Wheat (including flour)	113,797	115,398	− 1·39
Meat	15,868	18,026	− 11·97
Bacon and hams...	7,452	5,975	+ 24·72
Cheese	2,766	2,386	+ 15·93
Butter (including margarine) ...	5,376	5,748	− 6·47
Fruit	18,830	17,512	+ 7·53
Rice	9,573	4,840	+ 97·79
Sugar	35,029	38,356	− 8·67

In total weight of these food-stuffs, the quantity brought to our shores was rather larger in time of war than in time of peace. Yet one still occasionally meets a purblind pessimist who plaintively asks what the Navy is doing. This is a part of the answer. It is also a measure of the success of the much-advertised German "blockade" for the starvation of England. So absolute a triumph of sea-power in the first year of war would have been treated as a wild dream by the most confirmed optimist two years ago. The debt which the nation owes to our sailor-men is already immeasurable. That before the enemy is crushed the debt will be increased we may be assured. The crisis of our fate has not yet passed, and we may be called upon to meet worse trials than have yet befallen us. But in the Navy is our sure and certain hope.

"That which they have done is but earnest of the things that they shall do."

Under the protection of that silent shield the land may yield its increase untrodden by the invading foot, the trader may pursue his business undismayed by the threats of a thwarted foe, and the nation may rely that, while common prudence enjoins strict economy in husbanding our resources, sufficient supplies of food will be forthcoming for all the reasonable needs of the people.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Oxford at the beginning of Michaelmas Term, 1915, presents an unwonted appearance. The colleges are almost denuded of undergraduates; the river, playing grounds, and other usual resorts are comparatively deserted, and many of the accustomed activities are at a standstill. The city is redeemed from utter desolation by the presence of large numbers of young officers, who are sent here from their respective units to undergo a course of instruction by the staff of the Officers Training Corps, assisted by lecturers detailed from the War Office. Accommodation for this influx of the military element has been provided by several of the colleges, notably by Trinity, Wadham, Hertford, and Keble. The current number of the *University Gazette* contains a long list of members of the University who have given their lives for their King and country. Many of the scientific staff are being employed in researches and practical operations with direct reference to the war. Among these may be mentioned the names of Mr. R. B. Bourdillon, fellow of University, Mr. H. T. Tizard, fellow of Oriel, and Mr. I. O. Griffith, fellow of St. John's, who are all engaged in most important researches in the chemistry and physics of aerial warfare. Mr. Griffith has been specially re-elected to a fellowship in virtue of his research work in this department.

The new chemical laboratory, which is being erected under the supervision of Prof. Perkin, is rapidly approaching completion.

THE Swiney lectures on geology in connection with the British Museum (Natural History) will be delivered by Dr. J. D. Falconer, in the Lecture Theatre of the Victoria and Albert Museum, South Kensington, on Mondays, Tuesdays, and Saturdays, at 3 p.m., beginning Saturday, November 13. There will be twelve lectures, and their subject will be "Ice and the Ice Age." Admission to the lectures will be free.

A COPY of the current calendar of University College, Dublin, a constituent college of the National University of Ireland, has been received. It contains detailed particulars of the various courses offered in preparation for the degrees conferred by the National University. Among such degrees we notice the bachelor of agricultural science, bachelor and master of engineering, bachelor and master of architecture, and bachelor and master of commerce. In addition to other scholarships and exhibitions, the governing body is prepared to award not more than five post-graduate scholarships in arts or science.

THE Departmental Committee appointed by Lord Selborne under the chairmanship of Sir Harry Verney, Bart., M.P., to consider what steps can be taken to promote the settlement or employment on the land in England and Wales of sailors and soldiers, whether disabled or otherwise, on discharge from the Navy or Army, has presented an interim report recommending that as an experiment fifty men who have been discharged from the Navy or Army owing to disablement should be given a course of training in an agricultural college, with the view of obtaining for them permanent employment on the land, and, in the case of those proving specially capable, fitting them to become occupiers of small holdings. This recommendation has been approved by Lord Selborne, and endorsed by the War Office, and the Treasury has agreed to place funds at the disposal of the Board of Agriculture and Fisheries to defray the cost of the experiment. It is proposed that the men selected shall be sent to the Harper Adams Agricultural College, Newport, Salop, and to the College of Agriculture and Horticulture, Holmes Chapel, Cheshire, where they will be provided with board and lodging and be given a course of training in agriculture and horticulture free of charge to themselves. Any men who have been discharged from the Navy or Army on account of disablement, and desire to receive this course of training, should apply at once to the Secretary, Board of Agriculture and Fisheries, 4 Whitehall Place, S.W., for a form of application.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 11.—M. Ed. Perrier in the chair.—The President announced the deaths of Edouard Prillieux and Philippe Hatt, members of the academy.—L. **Lecornu**: The deformation of a cylindrical tube.—Henryk **Arctowski**: The solar faculæ. An account of a statistical study of Greenwich heliographic observations. From measurements of the areas of the spots and faculæ, the maximum for the latter is nine days behind the maximum for the spots. The author, from his researches on the Greenwich data, considers the phenomenon of the variation of the frequency of the sun-spots as being only a manifestation subordinate to the phenomenon of the variation of the faculæ.—Marcel **Brillouin**: Certain problems of mathematical physics in the case of hollow bodies.—Pierre **Lesage**: Salted plants and the transmission of acquired characters. Plants watered with salt water show differences, more or less marked, from plants of the same species watered with pure water. Starting with seeds of *Lepidium sativum* arising from plants watered with weak salt solutions in 1911, it is shown that some of the acquired characters are transmitted by the seeds, although the plants arising from the latter had been watered with soft water only.—E. **Demoussy**: The localisation of the acids and sugars in fruits. Various species of fruit, both ripe and partially ripe, were subjected to gradually increasing pressure, and the juices expressed collected in fractions and analysed separately. In some cases the amounts of acid and sugar vary considerably with the pressure. These variations are marked with apricots and grapes, small for peaches, and do not appear in strawberries and melons. The cause of this variation is discussed from the point of view of the osmotic pressures in the cells. The localisation of the dissolved matter in fruits is regarded as affording an explanation of the marked difference in the taste of certain fruits in the raw and cooked states.

THE UNIVERSITIES AND WAR ECONOMY.

MUCH anxiety has been caused in the educational world by the circular of date July 28 from the Lords Commissioners of the Treasury to those universities and similar institutions in Great Britain which are in receipt of Government grants. In consequence partly of this circular, and partly of the general need for economy in the expenditure of public funds, a letter of date August 26 has been addressed to the joint secretaries of the Committee on Public Retrenchment by the Vice-Chancellors of the four northern universities (Leeds, Liverpool, Manchester, and Sheffield).

The danger which threatens our universities is the more imminent because the Treasury circular appears to take a quite reasonable view of the situation. In consequence of the loss of students due to their enlistment, the colleges have suffered from a serious reduction both in the size of the classes and in the income received from fees. To compensate for the latter loss special supplementary grants were given to them last year. It is pointed out by the Treasury authorities that if these special grants are to be continued throughout the war, however prolonged, and all the institutions so aided are to be allowed to remain open, however low the attendance of students may be, the burden on public funds—which would increase progressively as young men continue to enlist—might prove ultimately to be very great and out of all proportion to the educational benefits conferred on the community. Acting on this assumption, the circular foreshadows a possible very considerable reduction in the amount which Parliament is to be asked to vote in the future. It is suggested that savings might be effected not only by leaving all vacancies unfilled (we understand that the University of London is to remain without a Principal on this account), but also by temporary suspension of institutions, classes, departments, or hostels where the attendance falls below a certain level, the staff thus released being provided with suitably remunerated work of some other kind more directly useful in the present emergency. The colleges are also asked to submit an estimate of their probable expenditure and revenue, and to point out the directions in which they are able to effect further savings.

If the efficiency of universities could be measured by the number of students that they turn out, there might be a valid justification for the opinions expressed in the Treasury circular. But the war by which Germany now seeks to cripple Great Britain, and the successful war which Germany has been waging against our commerce for the last quarter of a century without opposition, have placed on our Universities a burden of national responsibility which cannot be measured by mere numbers of students. There has probably been no period in the history of our country when so great a demand existed for enterprise and activity in our universities as during the present national crisis.

The letter of the northern universities affords a conclusive reply to the Treasury circular. It is accompanied by a statement of the active work which the colleges have undertaken in connection with the war. This statement is of a confidential character, but it may here be safely stated without any risk of assisting the enemy that it includes practically every branch of pure and applied science. In addition statistics are given as to the numbers of staff and students serving with the colours or engaged in munition work.

It used to be said that England's battles were won on the playgrounds of the great public schools, and it is still true that these are largely responsible for the magnificent performance of our men in the trenches. But it is equally true that Germany's war against the allied European Powers has been waged in the laboratories of the German universities. It is now being recognised that this is a war of brains and science. It is sufficiently unfortunate if the supply of scientifically trained students be reduced at the present juncture, but it will be still more unfortunate if a check is placed on their future activities, which would probably have a permanent and cumulative effect on our national development. If England is to win this war, England must also be prepared to maintain a struggle for power, which will certainly not cease with the conclusion of hostilities. We have heard much talk about "silver bullets," but Germany's silver bullets have to a large extent been supplied by Great Britain in exchange for chemical and optical goods and dyestuffs.

The contingents of the Officers Training Corps of the northern universities have already contributed more than 1000 officers to the Forces, and similar contingents have been furnished by other modern universities. It has been abundantly shown by the statements received from past students that they have found their university training of the greatest possible value in the field. There can be no better preparation for the

exigencies of modern warfare than a first-year course in physics, chemistry, and mathematics, varied in some cases by medical and biological studies, and if this course can be followed by a second-year course including physical applications of the infinitesimal calculus, so much the better. It is true that we have military colleges, but the instruction in these would appear to be carried on by rule-of-thumb methods to a greater extent than in our universities, and therefore less calculated to produce the type of individual who can think and act in an emergency.

But all modern university colleges are largely attended by women, and with a growing demand for women's work in posts hitherto occupied by men, some increase in the numbers of these students may be anticipated. In any case, it would be a fatal misfortune if anything were done which could in any way interfere with this side of the university work.

Even if our colleges were entirely depleted of their students, there would still be grave objections to a proposal for disestablishing and disendowing them. The claims of the professor who lectures only six or eight hours a week and devotes the rest of his time to research are very well put forward by Prof. Grant Showerman in the *Popular Science Monthly* for June, 1915, in an article entitled "The Liberal Arts and Scientific Management." A professor may receive fourteen dollars for every hour that he is down to lecture in the time-table, but it is pointed out that his connection with his work never ceases throughout the day or the year, and when this is taken into account his princely salary reduces to about 1.2 dollars per hour for expert service in a profession requiring unusually protracted preparation and involving social relations with the best paid classes of the community.

As soon as lectures are over, the average professor devotes his attention to research, and not only does he receive no remuneration for this work, but he frequently pays the cost of apparatus or publishes books at his own expense. Not only in the northern universities, but also in nearly every other university in the kingdom, laboratories and college staffs have been generously placed at the disposal of the Government. While the nation is paying high wages for unskilled labour, it is not only paying nothing for assistance the value of which may be reckoned in millions, but it is even receiving income tax and other dues from the donors at a rate calculated in many cases to place considerable anxiety on their shoulders.

The reason why the college professor engages in research, even at the risk of stinting himself and family in the necessities of life, is that he cannot help himself. He has an object to perform, and his happiness depends mainly on its accomplishment. It is certain that a falling off, should such occur, in the amount of class work would lead to an increased amount of research at a time when that research is urgently needed by the Government—more urgently needed than the Government or any similar body can possibly appreciate. Not only are mathematics, physics, and chemistry needed in connection with such varied applications as aeroplanes, wireless telegraphy, poisonous gases, periscopes, and explosives, but entomology, leather-making, economics, modern languages, botany, law, and history all have their uses in connection with the war.

The suggestion that certain members of the college staffs should be released and that they should be asked to find temporary paid work elsewhere, is one that ought only to be carried out with extreme caution. At the present time many professors and lecturers have undertaken temporary military or other duties, and the colleges are already effecting savings by the amounts of the salaries thus set free. It would thus appear that the system has already been adopted on a voluntary basis by the college staffs themselves. It is not evident from the circular whether, and if so how far, the Treasury contemplates the possibility of exercising pressure in the same direction, but we should be sorry to think that it has any desire to do so. Such an attempt would necessarily involve one of two alternatives, either "putting a round man into a square hole"—in which case good-bye to all the usefulness of his work, perhaps an irreparable loss to the community—or payment for research.

Now it would undoubtedly be of great advantage that persons engaged in valuable investigations should receive some compensation for the loss of income they may incur in carrying on the work. But it would be quite impossible for any Government at the present time to carry through any scheme which Labour leaders would distort into a proposal to put money into the pockets of the "idle rich." Even if this difficulty were overcome, payment for research would be sure to be made conditional on a clear statement being made as to the results aimed at and the practical uses to which they were to be applied. Now the main essence of research is that something has to be found out, the result of which is unknown, and it cannot be possibly anticipated at the outset what practical applications may arise. Any

attempt to place this work under a system of Government control and inspection would involve the exclusion of the important class of investigations which leads to the most novel and far-reaching results.

Our universities are straining their resources to the utmost in the effort to keep down expenditure. Where members of their staffs have gone on active service (in some departments to the extent of above fifty per cent.) their work is being cheerfully taken over by their colleagues. Not only are building operations being suspended (and this is probably a wise precaution for many reasons), but the purchase of books and apparatus is being reduced to the bare minimum.

The extra work undertaken by the remaining members of the staffs is only reduced in a very slight degree by the falling off in students. So long as a certain number of *classes* have to be held, a difference in the numbers of each class does not make a great difference in the work. The strain is bound to make itself felt sooner or later. But there are noticeable cases in which the effort to secure economy appears to have been carried too far. It cannot be desirable in the public interest that vacancies in two such important departments as physics and chemistry should remain unfilled, and we believe that it is in the interests of the Government, instead of bringing pressure on the universities to effect further economies, rather to exert its influence in checking them from going too far.

The four Vice-Chancellors of the northern universities are to be congratulated on the strong case they have made out. The matter is, however, one which affects all the modern institutions of university rank, and several of the statements in this article have been derived from independent sources. We hope that the action which is now being taken will prevent a mistake being made which must inevitably lead, sooner or later, to the realisation of the ideals of German militarism at the expense of Great Britain.

OLD-FASHIONED NATURAL HISTORY AND NEW-FASHIONED BOTANY.

(1) *The Hundred Best Animals.* By Lilian Gask. Pp. 304. (London: G. G. Harrap and Co., 1914.) Price 7*s.* 6*d.* net.

(2) *True Stories about Horses.* By Lilian Gask. Pp. 266. (London: G. G. Harrap and Co., n.d.) Price 3*s.* 6*d.* net.

(3) *The Human Side of Plants.* By Royal Dixon. Pp. xix + 201. (London: Grant Richards, Ltd., 1915.) Price 7*s.* 6*d.* net.

(1) THE stories of a hundred animals of distinction are told to two children by a veteran who had been a mighty hunter in his day, and good stories they are. He talked mostly about mammals—lion and tiger, seal and walrus, elephant and ape, camel and llama, antelope and deer, sloth and ant-eater, kangaroo and duckbill. But, like Solomon, the veteran spake also, in the last five of the twenty-nine chapters, "of fowl, and of creeping things, and of fishes." We are not sure that Solomon would always have agreed with him; for instance, about the water reservoirs in the camel's stomach; or as to the advisability of telling children that wise folk think the tallest animal in the world has lengthened out its neck by so much reaching; or that "squirts out" is the right word to use in regard to the exudation of toad's poison. But there is no doubt that the book is one which children will thoroughly enjoy and also profit by.

The talks are natural, interesting, instructive, with fresh news to tell, and with no tiresome "writing down." Just now and again the old Nimrod nods a little; for instance, on the last page when he says, in a way quite unlike himself: "We come to understand the highest examples of the different animals—call them best if you will—by comparing them with others of the same species below them in the scale, whether of physical strength and beauty or intelligence." He was also nodding when he said that the heron "is very scare in England now." But these are trivial matters; the important fact is that this is a thoroughly sound and successful book to be cordially recommended. It is adorned and illumined by a hundred excellent illustrations—often strikingly alive—from original photographs by A. F. W. Vogt.

(2) The second book from the same pen is also intended for young readers. It contains many well-told true stories about horses. We are told of the doctor's horse that defended its sleeping master; of the horse that fought and defeated the wolves it had been left to satiate; of an Arabian horse that twice saved a soldier's life; of a number of mares, some past foaling, which combined for six hours to lift the foals above the level of a flood; of a Shetland pony that saved a child from drowning; of a horse that kept a long vigil over a dead soldier; of another that lifted a little child out of harm's way, and of many more besides. As will be seen from the examples cited, the stories are of a homely, old-fashioned type, and we

are not surprised to find no reference to the "thinking horses" of Elberfeld. There are effective illustrations, and the printing of both books is such as suits both young and old eyes.

(3) Mr. Dixon has the courage of his anthropomorphism, which is of the deepest dye. For he maintains that plants "see, hear, taste, feel, walk, swim, run, fly, jump, skip, hop, roll, tumble, set traps, and catch fish; decorate themselves that they may attract attention; powder their faces; imitate birds, animals, serpents, stones; play hide and seek; blossom underground; protect their children, and send them forth into the world prepared to care for themselves—indeed, do all those things which we ourselves do. We now know that plants have even minds and souls, with which to think and to worship."

This is partly a rebound from a *hortus siccus* botany, partly an uncritical vitalism, and partly a somewhat saddening illustration of the lack of critical balance. Saddening, we call it, because the author has a fine series of most interesting facts to set forth concerning the intense vitality of plants, their movements, their sensitiveness, their adaptations, and their purposiveness (we do not say purposefulness), and yet he has gone and queered his pitch with an intolerably anthropomorphic and sentimental phrasing.

No one can be very enthusiastic over the botanist's terminology of chemotaxis, heliotropism, nyctinastic movements, and the like, but there should be some middle way between this and talking, as Mr. Dixon does, about the activities of plants as if they were on a plane with our own. We do not blame the author for regarding plants as psycho-physical beings—which seems to us a position which can offer a strong defence—nor even for speaking, if he wishes, about their senses (seven in number) and experiments, their "mentality and spirituality"; we blame him for leading the unwary to think that plants tackle the business of life on anything like human lines. For this will have to be unlearnt. Theirs is certainly *another way*, even farther from our understanding than instinct is.

TEXT-BOOKS OF PHYSICS.

(1) *Elements of Optics for the Use of Schools and Colleges*. By G. W. Parker. Pp. iv+122. (London: Longmans, Green and Co., 1915.) Price 2*s*. 6*d*.

(2) *Elementary Experimental Statics*. By I. B. Hart. Pp. vii+200. (London and Toronto: J. M. Dent and Sons, Ltd., 1915.) Price 2*s*. 6*d*.

(3) *Introduction to Heat*. By A. R. Laws and P. W. Todd. Pp. x+212. (London: Mills and Boon, Ltd., 1915.) Price 2*s*. 6*d*.

(4) *Experimental Harmonic Motion: a Manual for the Laboratory*. By Dr. F. G. C. Searle. Pp. x+92. (Cambridge: At the University Press, 1915.) Price 4*s*. 6*d*. net.

(1) IN Mr. Parker's "Elements of Optics" the subjects of reflection, refraction, mirrors and lenses, simple optical instruments, and dispersion are dealt with in four chapters. The book is intended for beginners, and no further mathematical knowledge is required for its perusal than an acquaintance with elementary geometry, simple algebraic equations, and the trigonometrical ratios. The text consists chiefly in the derivation of the usual formulæ of geometrical optics, the deviation method being employed for mirrors and lenses. The statements are accurate and concise, and the diagrams clear. Many teachers will regard the book as being too sparse and somewhat uninteresting owing to the absence of experimental matter. The inclusion of experiments to verify the laws and results by the aid of simple and inexpensive apparatus, would have enhanced the value of the book considerably. Numerical exercises are interspersed in the text, and answers are supplied.

(2) "Elementary Experimental Statics," by Mr. Ivor B. Hart, is written for pupils beginning the subject of mechanics. The mathematical knowledge assumed does not extend beyond an acquaintance with simple algebraic equations. The author deals with parallel forces, centres of gravity, inclined forces, friction, and the simple machines. The chief elementary facts are impressed on the pupil by a series of simple experiments. Full directions for the performance of these experiments are given, and the method of recording the results is indicated. It is better to insist on the tabulation of actual observations than results obtained after a mental calculation, as in col. 5 of the table on p. 45. The book is provided with a large number of questions and numerical exercises. The pupil who performs the experiments and works the examples in this book will have laid a good foundation for further study in experimental science.

(3) "Introduction to Heat," by Messrs. Laws and Todd, may be used both as a class and laboratory text-book in schools. The aim of the authors has been to introduce many phenomena from everyday life, and by appealing to the ordinary experiences of the pupil to awaken an intelligent interest in the subject. The order of treatment is somewhat different from that usually adopted in text-books of this character. The opening chapter

deals with conduction and convection of heat, and this is possible because at such a stage only a descriptive treatment of these subjects can be attempted. Other sections of the book deal with the barometer and thermometer, expansion, evaporation and condensation, hygrometry, fusion and solidification, specific heat, radiation, heat and work. Certain paragraphs are to be omitted on first reading.

Speaking generally, the authors have succeeded in producing an interesting text-book, but in many places the statements are loose and not characterised by that precision of language which it is so essential to inculcate in the mind of a beginner. Thus on p. 19 the authors speak of the pressure due to 60 c.c. of water, and on p. 88 define the British unit of heat as "the quantity of heat required to raise 1 lb. of water 1° F." This omission of "the temperature of" is a common occurrence in the text. Again on p. 20 we have an experiment "To determine how much 1 c.c. of air expands when heated." In this the temperature of 160 c.c. of air is raised from 15° C. to 85° C., the amount of expansion being 40 c.c. The calculated expansion of 1 c.c. is $40/(160 \times 70) = 1/280$. The authors then state: "an accurate and at the same time convenient result is 1/273." On p. 140 paraffin-wax is not a suitable material to illustrate melting point by the curve of cooling. In the diagram on p. 40 the pressure gauge should be connected to the inner cylinder of the hypsometer. The book contains a large number of questions and numerical exercises.

(4) Dr. Searle's "Experimental Harmonic Motion" is written on lines very similar to his well-known manual on "Experimental Elasticity." The subject-matter dealt with, however, is not so wide as the title would seem to imply. The first part of the book is devoted to the elementary theory of harmonic motion, and is apparently carried only so far as is necessary to understand the experiments described in the second chapter. There is no discussion of damped vibrations, composition of harmonic motions, or the analysis of periodic curves. The experiments described in the second chapter (fourteen in number) are such as are performed in the author's classes at the Cavendish Laboratory. They include oscillation methods for comparing moments of inertia, determinations of the acceleration due to gravity, the experimental study of a pendulum with yielding support, and an investigation of a system with two degrees of freedom. A theoretical discussion of each experiment is given, and there are full practical details for the design of the apparatus to ensure satisfactory results. Each experiment is furnished with a typical series of data obtained in an actual experiment. The exposition is clear, and the book may be profitably read by university students. Many teachers will welcome a book of this kind on account of the precise details for the setting up of the various experiments.

LABORATORY WORK ON COAL AND COAL-PRODUCTS.

Laboratory Work for Coal-mining Students. By J. Sim and A. M. Wylie. Pp. viii+136. (London: E. Arnold, 1915.) Price 2*s*. 6*d*. net.

THE difficulties associated with coal analysis are determined in part by the fact that a material which is consumed in tons has for convenience of manipulation to be tested in grams, and in part by the variety of uses to which coal is applied. The first necessitates merely extreme care and method in sampling, but the second requires a diversity of tests demanding the greatest skill and experience. The most satisfactory way of conducting a test is obviously to submit a large sample of the material to the special process to which it is subsequently to be applied. This is frequently done; but it is not described in the present volume, which is concerned with laboratory methods only.

The difficulties attending coal analysis may be realised when one considers the variety in composition as well as the chemical sensitiveness of the substance. Coal is no sooner exposed to the air than it begins, especially when in powder, to absorb oxygen and to evolve carbon monoxide and dioxide. The sulphur which is present, partly as organic sulphur and partly as pyrites, also undergoes oxidation. Then, again, the nature of the products and by-products, upon which its value in the gas and coking industry depends, is determined by the character of the coal as well as by the temperature at which these products are extracted or distilled. For example, it has been shown recently that extraction with pyridine removes considerable quantities of paraffins, that distillation *in vacuo* gives rise to a series of naphthenes (cycloparaffins), whilst ordinary destructive distillation at high temperatures produces the coal-tar hydrocarbons. It would appear from this that the original hydrocarbon of the coal passes through various stages in the process of heating. Finally, a knowledge of the thermal value of the coal when used as fuel is essential. It will be seen that the investigation of a sample of coal is not a simple affair.

The present volume has been written with the object of facilitating the laboratory work of a coal-mining student, that is, one who is studying the scientific basis of the industry from every point

of view. It is divided into five chapters, the first two being concerned with the coal itself, the second two with the products, namely, oil tests and gas analysis, and the final chapter with fan and ventilation tests.

The volume has evidently been put together with great care by its authors, who have had practical experience of their subject. The description of the apparatus and methods is clear and concise, and illustrated by diagrams and by actual examples, so that the student should have no difficulty in carrying out the different operations. J. B. C.

OUR BOOKSHELF.

Some Frontiers of To-morrow: An Aspiration for Europe. By Prof. L. W. Lyde. Pp. viii + 120. (London: A. and C. Black, Ltd., 1915.) Price 2s. 6d.

IN this small volume Prof. Lyde makes suggestions for the settlement of European frontiers after the war. Three considerations are laid down as of vital importance: (1) that the frontier should be associated, not with war, but with peace; (2) that the unit of area should have some direct relation to national sentiment; (3) that inability to assimilate should disqualify any Power for territorial expansion. The first suggestion is the most important. Prof. Lyde maintains that frontiers should be identified with features related to the meeting of people in the ordinary routine of peaceful intercourse. If this be true, it follows that a navigable river makes the best frontier. A defensive frontier—the type of frontier of the past—will never put an end to conflict between neighbours, but may even promote it. An inhabited, in contrast to an uninhabited, frontier belt encourages contact between adjoining people, discourages racial and cultural antagonism, and so minimises the chance of friction, and promotes civilisation. Prof. Lyde is always stimulating, even if he fails to convince at times. His book is crammed with ideas from beginning to end, which should attract the attention of statesmen. But it will be hard to convince those who have treaty making in their hands that accurate scientific knowledge is a real asset in the matter, and that the geographer is the expert who has the knowledge and should be consulted.

R. N. R. B.

Liverpool Marine Biology Committee. L.M.B.C. Memoirs on Typical British Marine Plants and Animals. Edited by Prof. W. A. Herdman. xxiii. Tubifex. By G. C. Dixon. Pp. viii + 100 + 7 plates. (London: Williams and Norgate, 1915.) Price 3s. 6d.

Tubifex rivulorum is a slender Oligochæte, not more than two inches long, often found in large numbers in the mud of rivers and streams, but it occurs frequently also in brackish tidal waters, and therefore a memoir on this worm is appropriately included in a series dealing with marine animals. Of the aquatic Oligochætes, Tubifex is the type usually chosen for study in advanced classes in this country. Accounts of the different systems of organs have appeared in various zoological publications, but for figures of the worm the student has hitherto been dependent chiefly on the memoirs of d'Udekem (1855) and Vejdovsky (1884). Miss Dixon has revised and extended the previous accounts, with the result that her memoir gives a careful and reasonably full description of the structure of the worm, illustrated by seven well-drawn plates, of which the first in particular will be useful to the student.

After a few general remarks on the habits of the worm, an account is given of the external features and of the various systems of organs, the hermaphrodite reproductive apparatus being described in considerable detail, almost one-half of the memoir being devoted to this group of organs. Of considerable interest is the discovery that Tubifex possesses dimorphic spermatozoa. Both kinds of spermatozoa are of the elongate type and are tailed, but they differ in size and in the proportions of their parts. In the ordinary spermatozoa the head forms about one-sixth of the total length. The second type of sperm is about three times as long as the ordinary one, and the head forms about one-half the total length.

A good account is given of the remarkable spermatophores of Tubifex, which are moulded into their characteristic form in the spermathecal duct.

The memoir concludes with a brief reference to the parasites of Tubifex and a bibliography.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Distances at which Sounds of Heavy Gun-firing are Heard.

REFERRING to the correspondence on this subject, I have been collecting information as to places at which the sound of the firing in Belgium has been heard in this country.

I have undoubted records of its having been heard at many places throughout the south-east of England (all of them in Essex, Kent, Sussex, or Surrey), and am giving the result of my inquiries in a paper to be read before the Essex Field Club on October 30. Here, at a distance of about 125 miles from Ypres (taking that town for convenience, as a known centre), I have heard firing quite unmistakably since the beginning of the war—often all day, and for many days in succession, and frequently at night too.

So far as I have been able to ascertain, the greatest distance from Ypres at which the firing has been heard unmistakably is about 140 miles, though I have a less satisfactory record up to 150 miles. No doubt, however, it has been heard further in favourable conditions. Observations seem to show that the direction of the wind has less to do with the transmission of the sound than certain atmospheric conditions, though it is not easy to ascertain exactly what these conditions are.

My house here stands in a fairly open and elevated position, about 155 ft. O.D., with no higher ground in the immediate vicinity, or between me and Ypres. Many of my neighbours, who live in similar situations, also hear the sound, and recognise clearly what it is. It seems much less audible at lower elevations, and quite inaudible among houses. For instance, I cannot hear of its ever having been heard in the adjacent town of Chelmsford, or in any part of London.

Chelmsford, October 19.

The Cumberland Earthquake of October 2.

I WAS interested to read the note in NATURE of October 21 (p. 208) referring to an earthquake in the Lake District, Cumberland, on October 2, at 3.15 a.m. My wife and I spent some weeks at Seatoller, Borrowdale, leaving on October 2. Early in the morning of that day we were awakened by a strange noise and the house vibrating. The noise and vibration were so completely similar to what occurs in my own house when the hot-water boiler is overheated and steam, condensing in the pipes, causes "hammering," that I was on the point of getting up to turn on the bathroom tap, when it ceased. As we were leaving in the morning the proprietors inquired if we had heard the noise in the night, and I replied at once that I had heard the hammering in the pipes of the hot-water system, but was told that it was quite impossible for the water to have been hot at the time. I had no idea of the true explanation until I read the note referred to. Seatoller is about 30 miles S.S.W. of Carlisle and 4½ miles N.N.E. of Scafell Pike. Possibly it may be of interest to record that at this place the earthquake was accompanied by concussions and vibrations sufficient to waken the inhabitants.

FREDERICK SODDY.

October 23.

The Etymology of "Chincough."

WHOOPING-COUGH is, or used to be, called in the south of Scotland, "chincough," but the "ch" was hard, so that it sounded kincough, or kink-cough. In Jamieson's Scottish Dictionary the word "kink" has the meanings (1) a violent fit of coughing attended with suspension of breathing, (2) a regular fit of the chincough. "To kink" is to labour for breath in a severe fit of coughing. The more purely Scottish word for whooping-cough is "kinkhost," in the Belgic language *kink-hoest*.

L. B.

October 23.

THERE can, I think, be no doubt that "chincough" is a good English word, meaning whooping-cough and nothing else. It has nothing to do with *chien* (a dog), as Mr. Hart supposes (NATURE, October 21), or with chin, although to anyone who has noticed the depression and thrusting forward of the lower jaw during a paroxysm this derivation might seem probable. The word is, according to Skeat, properly chink-cough, and in Scotland and some parts of England a paroxysm is called a kink, which, again according to Skeat, means a catch in the breath, from kik, or kuk, to gasp, an imitative word, which is also the base of cough. The term kinkhost, still in use in Scotland, resembles the German equivalent, *keuchhusten*, which is also imitative. The French *coqueluche* is more puzzling, but probably has reference to the crowing inspiration which follows the expiratory spasm.

DAWSON WILLIAMS.

London, October 22.

As your correspondent (NATURE, October 21) points out, chincough has certainly nothing to do with "hiccough"; but has it anything to do with the French *chien* = a dog, as he supposes? Chincough is the softer English equivalent of the Scotch kink-host (Dutch, *kink-hoest*). Besides, the noun there is also the verb, to kink (O. Dutch, *kinken* = to cough), and even an Englishwoman, at least in the north, who calls the disease whooping-cough, will tell one when her child began to "kink" with its cough. My dictionary compares the word with the Anglo-Saxon "cincung" = a fit of laughter, and kink is sometimes also used in that sense, or in connection with any choking inspiratory spasm. Finally, there is nothing in the sound of whooping-cough to suggest a dog, though the cough of croup might do so.

SCRIVEN BOLTON.

CHINESE DEFENSIVE ARMOUR.[1]

THE somewhat ponderous title of the work before us rather obscures the subject of this monograph, which is upon the origin and history of defensive armour, a theme of considerable cultural importance and here treated systematically for the first time. As a result, we have a masterly description of Oriental protective armour, and suggestive fresh light is also thrown upon certain sources of early Chinese civilisation.

The research is based primarily upon a large collection of ancient Chinese clay figures dug up (apparently by the author) from graves in the provinces of Shen-si and Ho-nan during the years 1908–1910, and deposited among the rich collections from the Far East now in the Field Museum of Natural History at Chicago, of which the author is a well-known curator and field-explorer.

The hides of the archaic Chinese cuirasses of the pre-metal age are ascribed by ancient tradition to two animals named respectively *Se* and *Si*, which are identified by the majority of sinologists with one or two species of rhinoceros. Dr. Laufer, who combines with his scientific physical training also a scholarly knowledge of Chinese, revises the Chinese texts at first hand, and appears to substantiate his identification of the *Se* as the single-horned and the *Si* as the two-horned Sumatran rhinoceros. In addition to the mass of mythological and folk-lore references to

[1] "Chinese Clay Figures." Part i., Prolegomena on the History of Defensive Armour. By B. Laufer. Field Museum of Natural History Publication 177, Anthropological Series, vol. xiii., No. 2. Pp. 69–315+64 plates. (Chicago: Field Museum of Natural History, 1914.)

these animals extracted from ancient literature and art, Dr. Laufer has elicited historical references to these animals, as royal presents and otherwise, in the official annals, which are important as indicating some chronology for the former geographical range of these animals in northern China and central Asia, where they have long been extinct. It appears that the two-horned (or Sumatran?) rhinoceros no longer existed within China proper in the first century A.D., and was only to be found to the south of the Yangtse; while the one-horned species survived in China in the Upper Yangtse valley down to the Middle Ages. In connection with the former range of these animals we would suggest that the Arabic name "*Kargadan*" is obviously cognate with the Indian title for the rhinoceros, which in the Sanskrit is "*Khadga*," which means literally "the cutter," or "sword," evidently with reference to the horn.

Fig. 1.—Eskimo armour of ivory plates and fragment of iron plates. From "Chinese Clay Figures."

The association of the rhinoceros with the myth of the unicorn is examined in great detail; also the mystic use of the horn as anti-poison goblets up to the present day in China. It appears to us possible that this latter use was derived from India, or at least through false etymology by confusing the Sanskrit name for "horn," namely *Vishāna*, with the Sanskrit word for "poison," namely, *Visha*; for the Chinese are known to have called the rhinoceros-horn in the eleventh century A.D. by the name *pi-sha-na* (Wylie, "Notes," 195), their version of the Sanskrit word. This false etymology would also readily lend itself to the astrological view that the horn of the rhinoceros symbolised the ascending node, and as such represents hostility to the powers of darkness, and as a poison-destroyer. In this regard it is perhaps noteworthy that there seems to us a suggestion of purity also (or is it phallic?) in respect to the armorial unicorn, which, according to the legend, was only to be caught at the lap of a

Fig. 2.—The animal "*Si* resembling swine" (from the illustrated edition of *Erh ya*). From "Chinese Clay Figures."

virgin maid. It is clear, however, that Pliny ("Nat. Hist.," 8, 21), who must have been

familiar with the rhinoceros in the circus, did not identify it with his fierce *mono-ceros* or unicorn.

In connection with the use of rhinoceros hide as armour, it is recalled that it is only when the skin is dried and properly prepared that it becomes of iron-like hardness; for the skin of the living animal, notwithstanding popular hunters' tales to the contrary, is quite soft and can be readily penetrated in any place by a bullet or easily pierced by a hunting knife.

We have not space here to follow the author in his exhaustive account of the origin and development of defensive armour. He treats of this in long chapters devoted to "Defensive Armour of the Archaic Period" (B.C. 1122–255), characterised by hide cuirass and scale armour in which metal was absent; "Defensive Armour of the Han Period" (beginning in the third century B.C.), when metal (at first copper and latterly iron) scales were introduced, from Persia, Dr. Laufer believes, to form "plate" armour; "Chain and Ring Mail," also from Persia, though this was confined to the Arabs and Moghuls and Tibetans, and never adopted by the Chinese; "Plate" armour, which was much more ancient and at first formed of bone-plates; "Sheet" armour, as in the medieval West, first came into use in China in the Tang period (A.D. 618–906), and from India, the author seems to believe. A chapter is also devoted to "Horse-Armour," shedding much new light upon this interesting phase of protective armament.

A word of high praise must also be given to the illustrations, which are well chosen and significant; and the photographic plates, sixty-four in number, are beautifully reproduced.

L. A. WADDELL.

MODERN BULLETS IN WAR AND SPORT.

FOUR interesting articles appeared in the columns of *Engineering* in August of this year, contributed by Fleet-Surgeon C. Marsh Beadnell, and these have now been reprinted in the form of a thin pamphlet. The articles are full of information as to the weights and velocities of different bullets and as to the effects of bullets of different kinds when they strike various substances at different points in their trajectory. The great experience of the author as a big-game sportsman on the one hand and as having seen many cases in the South African and Philippine wars and the present war on the other give great value to his observations on the destructive or at times very slight effects produced by the modern bullet; his treatment of the dynamical and especially of the aërodynamical principles affecting the motion of projectiles is less satisfactory.

In dealing with the effects of bullets the author shows how the damage done depends on the energy lost by the bullet; how, for example, a bullet at a high velocity and striking properly end-on may drill a clean hole, doing the minimum of damage and losing but little of its velocity, while at a later stage of its flight when travelling more slowly, and especially if in any degree inclined to its trajectory, the destruction is incomparably greater, and the loss of energy as represented by v^2 equally so.

The following experiment will exemplify this fact:—Two skulls were filled with a substance of a consistency as near as possible to that of the brain. Against the one was fired a normal bullet at high velocity, against the other a similar bullet at low velocity, this being effected by using a quarter charge; the range in each case was 10 ft. The first skull was neatly perforated, and the bullet, unaltered in shape, was found embedded 26 in. in the wood backing; the second skull was partly disarticulated, and was fractured posteriorly, the bullet lying inside against its posterior wall. In the case of the first skull the bullet parted with but little of its energy, and that only at the actual points of entry and emergence. In the case of the second skull more of the bullet's energy, both absolutely and relatively, was expended on it and its contents.

In an experiment of this sort a good deal depends on the compressibility of the material filling the envelope. As illustrating this point it may be permitted to refer to an experiment made by the writer of this notice at the time that he was photographing bullets. In order to ascertain if it would be practicable to photograph a bullet glancing off still water, he constructed a long trough of thin wood open at the top, somewhere about 3 ft. long and 4 or 5 in. wide and deep, and on to the water in this he fired a 0·303 bullet at as near a grazing incidence as he could. The water was hit about two-thirds along the trough, and was driven out as by an explosion. The front and sides of the trough in advance of the point of striking were split into matchwood, and generally, apart from the photographic difficulties, it seemed desirable to experiment in other directions.

The author has experimented on the inclination at which the modern high-speed bullet will penetrate a skull, and found that at angles above 5° or 6° he obtained penetration, whereas Snider and Martini bullets would glance off at much greater angles. Space does not allow of reference to the numerous valuable observations of the author on the curious effects of bullets both in big game and in warfare. These will be read with the greatest interest. It is not possible, however, to follow the author in his excursions in the domain of pure dynamics, and his treatment of the action of the air on the projectile appears to the writer to be very largely imaginary and incorrect. So difficult a subject as the action of air upon a rotating projectile, whether spherical or elongated, and whether the axis of spin is in or across the trajectory, scarcely admits of any but the most rigid treatment, and in this the author might find Mr. Crabtree's admirable book illuminating. There is a statement which is new to the present writer, and it would have been well to have given the authority.

Thus, up to speeds of 790 ft. per second resistance varies as the square of the speed, between 790 and 990 ft. per second as the cube, between 990 and 1120 ft. per second as the sixth power, between 1120 and 1330 ft. per second again as the cube, and above 1330 ft. per second again as the square of the speed; above 1500 ft. per second the relationship is not known.

C. V. BOYS.

PROF. VIVIAN B. LEWES.

WE much regret to see the announcement that Prof. Vivian B. Lewes died on October 23, of pneumonia, at Mold, Flintshire, where he was to deliver one of a series of Gilchrist Lectures on explosives.

Prof. Lewes was born in 1852. His education was undertaken by his uncle, George Henry Lewes, the well-known author of the "History of Philosophy" and other works. On leaving University College School at the age of sixteen, he became assistant to Dr. F. S. Barff, and in 1870 to Prof. A. W. Williamson at University College. Later he worked under Dr. C. Graham at the Birkbeck Institute, and was appointed assistant at the Royal Naval College, Greenwich, in 1879, where he succeeded Dr. H. Debus as professor of chemistry in 1888, which post he resigned a year ago. He was appointed chief superintending gas examiner to the corporation of the City of London in 1892, and at the time of his death was chairman of the Chemical Section of the Munitions Inventions panel.

His chief scientific work was on the action of heat on hydrocarbons and the cause of luminosity of flames; papers on these subjects were published in the Proceedings of the Royal Society in 1893–1895. Lewes's acetylene theory of luminosity, whilst it has met with much criticism, has been accepted widely as the correct explanation of the main interactions giving rise to luminosity. He was also the author of papers on pentathionates.

When, in 1892, Willson, in Canada, first obtained calcium carbide on a commercial scale, a sample was forwarded to Lewes, who, at the Royal Society of Arts, in 1894, brought this substance under the notice of an English audience. Later he did much to establish the success of the new industry. No one, indeed, was more welcome or more certain of an appreciative audience at the Society of Arts, and there he delivered several series of Cantor and other courses of lectures, dealing with such subjects as coal gas, explosives, liquid fuel, etc.

As a lecturer under the Gilchrist Educational Trust he was most popular and widely known throughout the country. He was, indeed, the last of the original group of Gilchrist lecturers, the panel of which included many illustrious names.

Prof. Lewes did excellent pioneer work in connection with the University Extension lecture scheme and as a lecturer for the Technical Education Committee of the London County Council. This was the work largely of a past decade, but filled a most important place in our educational system. He laid claim justly to have instilled the desire for further chemical knowledge in numbers of young students, and contributed very greatly to the success of systematic chemistry courses in our numerous technical schools and institutions.

His connection with the Navy was naturally not without its influence on his researches, many of which formed the subject of communications to the Institution of Naval Architects (of which he was a vice-president). The institution awarded him its first gold medal for a paper on "The Formation of Boiler Incrustations and Oily Deposits." Other important papers were on the corrosion of metals, anti-fouling compositions, and the spontaneous ignition of coal.

Prof. Lewes's principal technical field, however, was in connection with coal gas. He was always a welcome lecturer at the Institute of Gas Engineers and other similar societies, before the members of which he dealt in a lucid manner with current problems affecting this important industry. He was the author of several books, including "Acetylene," which is a standard work of reference, "Service Chemistry," now in its fourth edition, "Liquid and Gaseous Fuel," and "The Carbonisation of Coal."

Prof. Lewes's genial personality, his kindly and generous nature, endeared him to a very wide circle, both of personal and professional friends. Among the large number of naval officers with whom his duties brought him in contact no one was more popular or more respected.

NOTES.

WE much regret to announce the death, on October 23, from heart failure following influenza, at fifty-one years of age, of Dr. R. Assheton, F.R.S., University lecturer in animal embryology at Cambridge since 1911.

WE regret to announce that Sir Andrew Noble, Bart., K.C.B., F.R.S., to whose scientific work on artillery and explosives the marvellous developments of heavy weapons within the last fifty years are chiefly due, died on October 22, at eighty-four years of age.

MR. W. MARRIOTT has retired from the post of assistant secretary of the Royal Meteorological Society held by him for the last forty years, and has been succeeded by Mr. A. H. Brown, the chief clerk of the society.

MR. W. K. CARR, the owner of one of the best-equipped private laboratories in the United States, died recently at his home in Washington, at the age of fifty-five. On leaving the University of Virginia in 1878, he spent twelve years in the sale and manufacture of cotton at Norfolk, Va. Since then he had devoted most of his time to scientific research.

THE death is announced, in his sixty-fifth year, of Mr. C. F. Holder, of Pasadena, the writer of a large number of books on the natural history of southern California. He was educated at the Friends' School, Providence, R.I., and at the United States Naval Academy. For a few years he was an assistant at the American Museum of Natural History, New York. Mr. Holder's special interests were in marine zoology.

THE first meeting of the new session of the Geological Society will be held on Wednesday next, November 3, at 5.30 p.m., when Dr. C. W. Andrews will exhibit photographs and give an account of the

discovery of a fossil elephant at Chatham. Owing to the possibility of air-raids over the metropolis, and the consequent disorganisation of traffic, the council has decided that the time of the evening meetings shall be changed temporarily from 8 p.m. to 5.30 p.m.

WE regret to record the death of Lieut. J. Gordon Hollingsworth, of the 10th Battalion of the Middlesex Regiment, who was killed in the Gallipoli Peninsula on August 12. He was the second and only surviving son of Mr. A. T. Hollingsworth, one of the managing directors of *Engineering*. He was reported "missing" some weeks ago, and it was only on October 15 that official announcement was made that he fell gallantly leading his men in an advance which took place soon after the landing at Sulva Bay. He was educated as an engineer, and joined the staff of our contemporary, being later elected a director of *Engineering*, Ltd.

IN a review of Dr. E. Hindle's book on "Flies in Relation to Disease," published in *Science* for July 16, the remark was made that the author had been killed in Africa. Referring to this statement, Prof. G. H. F. Nuttall writes from Cambridge:—"Dr. Hindle has never been in Africa, and he is alive and well. He is expecting to leave for the front at any moment as a divisional signal officer in the R.E. I shall be much obliged to you if you will help me to make the facts known, as the statement in *Science* has caused unnecessary pain to Dr. Hindle's friends in many parts of the world."

A CORRESPONDENT, writing from Amsterdam in the *Times* of October 22, contributes incidentally some interesting observations on the effects of distant gun-firing. "At more than one point in the southern frontier" of Holland, he says, "one hears the guns from the French front," the distance being about a hundred miles. "It is difficult to say whether one really hears them with one's ears or whether one feels them. It is not, at this distance, a definite sound so much as a jarring and throbbing of the air. But it is audible, or sensible, enough that one can pick out the detonations of pieces of different calibre, the almost continuous low muttering (for heavy work was going on) of the smaller guns being punctuated at intervals with the double shock of something much bigger."

AT the annual statutory meeting of the Royal Society of Edinburgh on October 25 the following were elected as council:—*President*: Dr. J. Horne; *Vice-Presidents*: Prof. F. O. Bower, Sir T. R. Fraser, Dr. B. N. Peach, Sir E. A. Schäfer, the Right Hon. Sir J. H. A. Macdonald, and Prof. R. A. Sampson; *General Secretary*: Dr. Cargill G. Knott; *Secretaries to Ordinary Meetings*: Dr. R. Kidston and Prof. A. Robinson; *Treasurer*: Mr. J. Currie; *Curator of Library and Museum*: Dr. J. S. Black; *Councillors*: Principal A. P. Laurie, Prof. J. Graham Kerr, Dr. L. Dobbin, Dr. E. M. Wedderburn, Dr. W. B. Blaikie, Principal O. C. Bradley, Dr. R. S. MacDougall, Dr. W. A. Tait, Dr. J. H. Ashworth, Prof. C. G. Barkla, Prof. C. R. Marshall, Principal A. Crichton Mitchell. Sir William Turner, former president, is a permanent member of council.

IN addition to the awards announced in April for papers read at the meetings, the council of the Institution of Civil Engineers has made the following awards for papers published in the Proceedings without discussion during the session 1914–15:—A Telford gold medal to Mr. James Forgie (New York); Telford premiums to Messrs. J. R. Mason (Dunedin, N.Z.), Harold Berridge (Aden), C. R. White (London), C. S. Churchill (Roanoke, Va.); and the Trevithick premium to Mr. A. Poulsen (Lemvig, Denmark). The Indian premium for 1915 has been awarded to Mr. C. W. Anderson (Midnapore, India). The ninety-seventh session of the Institution will be opened on Tuesday, November 2, at 8 p.m., when Mr. Alexander Ross, president, will deliver an address, and will present awards made by the council for papers read and discussed or otherwise dealt with during the past session.

A MEETING of the National Illumination Committee of Great Britain was held on October 20, when Mr. W. Duddell was elected chairman of the committee in succession to the late Mr. Edward Allen. Reports on observations carried out at the instance of the committee at a number of technical laboratories, on the height to which the flame of the Hefner amylacetate lamp should be raised to afford a light of one international or English standard candle, were discussed, and their further consideration was postponed until fuller details of some of the observations and other reports which had been promised had been obtained. A report prepared and sent by Dr. E. Ott, of Zürich, on researches which had been carried out in Switzerland on the effect of atmospheric pressure, humidity, and vitiation on the light afforded by the Hefner standard lamp was considered, and it was decided, subject to Dr. Ott's consent being obtained, to prepare a translation of the report for communication to the British technical Press.

THE *Mining Magazine* of October 14 contains an article on weights and measures dealing in a practical manner with the question of the necessity for some reform in our present system. The substitution of the metric system is advocated, but more from the point of view of the technical man than from that of the general trading community. It is pointed out that the modifications which the adoption of the metric system would introduce in mining and metallurgical work are not such as to cause any inconvenience, while on the other hand the confusion which at present exists owing to the various tons, gallons, etc., recognised in the mining profession would be entirely obviated. It is also suggested that if the adoption of the metric system is regarded as too revolutionary for the English-speaking nations, or if the present is not a suitable time for conducting an agitation in its favour, some steps can at least be taken by technical men towards simplifying the British system and agreeing upon a common usage. Various examples are given with the object of illustrating the need for a less complicated and more practical system. The general adoption of the short ton, which is much used in mining circles for recording ore mined or developed, is strongly advocated. Engineers are advised to use the metric

system wherever possible, and always to champion it; to use the simplest of English weights and measures and in cases of uncertainty to specify the unit; and further, to avoid, when addressing an English audience, the use of denominations of weights and measures not likely to be understood.

THE civil engineering profession, and especially that section of it connected with river training and coastal defence work, will learn with regret of the death, at the age of eighty-three, of Mr. W. H. Wheeler, formerly of Boston, Lincs, but latterly residing at Bromley, Kent. He practised for many years in the district bordering on the Wash, and became an authority on the drainage of fens and low lands, and the regulation of estuary channels, as also on coastal phenomena generally. His "History of the Fens of South Lincolnshire" is, perhaps, his best known work; it was first published in 1868, and was reissued as a second edition in 1897. Other volumes which followed were "Tidal Rivers: their Hydraulics, Improvement, and Navigation," in Longmans's Civil Engineering Series, 1893; "The Sea Coast: (1) Destruction, (2) Littoral Drift, and (3) Protection," 1902; a "Practical Manual on Tides and Waves," 1906; and "The North Sea: Physical Characteristics, Tides, Currents, and Fishery," 1908. His pen was very prolific, and he contributed a great number of papers to professional societies and articles to technical journals, as well as to our own columns, all bearing on the branch of work which he had made peculiarly his own, and on which, despite inevitable occasional divergences of opinion from professional colleagues on controversial matters, he was ever listened to with attention and respect. He was elected a member of the Institution of Civil Engineers in 1867, and was the recipient of a Telford premium from that body.

A FEW further particulars are available as to the recent long-distance tests in wireless telephony in the United States to which reference was made in NATURE of October 7 (p. 155), but no data have yet been disclosed concerning the type of apparatus employed in the tests. The transmitting apparatus was installed in the U.S. Government wireless station at Arlington, while receiving sets only were used at Mare Island and Pearl Harbour stations. The distance between Arlington and Mare Island is about 2500 miles, and between Arlington and Pearl Harbour 4900 miles. The conversation was overheard at several points, including Darien, Panama, a distance of more than 2000 miles from the transmitting station. The tests are the outcome of many years of painstaking experiments. Early in the spring of this year the system had been developed up to a point where good results were secured over a distance of 250 miles, employing for the aerial an experimental tower erected at Montauk Point, Long Island, and a small tower at Wilmington, Del. This was followed by tests between Montauk Point and St. Simons Island, Ga., a distance of 1000 miles. No novel features are claimed for the system, which is said to be simply the perfection of existing methods. Further and extended trials under varying conditions are necessary, however, before we can state with tolerable certainty whether the problem of long-distance wireless telephony has been satisfactorily solved.

THE Trustees of the National Museum, Melbourne, have issued a second and revised edition of the "Guide to the Ethnological Collections," compiled by Dr. Baldwin Spencer. The older specimens are largely due to Mr. Brough Smith, but they have been largely increased by those made by Dr. Spencer and the late Mr. Gillen in the course of their famous journeys among the Arunta and other tribes. A short introduction gives the latest views on the ethnology of the continent. Specially remarkable are the rare specimens illustrating religious usages, totemism, initiation ceremonies, and the like. The handbook, which is well illustrated, will be indispensable to all students of the Australian aborigines.

MR. MORTEN P. PORSILD, writing from Disco, Greenland, has published a valuable monograph entitled "Studies on the Material Culture of the Eskimo in West Greenland." He adopts the scientific method of discussing in the case of each implement the object aimed at in its construction; the mode of use in order to attain this object; how its form is adapted to its use; how far the nature of the material has influenced its form. He points out that the study of Eskimo culture is specially useful for comparison with that of the European Stone Age people. He concludes that this culture developed in the Arctic area without any borrowing from foreign civilisations, except in the case of the bow and arrow. He finds that the types of the kayak have a regional distribution similar to that of the Greenland dialects. Many implements are for the first time described, and these notes serve to modify certain current theories. He warns museum collectors against the purchase of so-called "models," and he remarks that though faked antiquities are very rare, yet they may be sometimes met with.

OF pelagic Annelids, the Alciopidæ and the Tomopteridæ, not a single species has hitherto been obtained from Japanese waters. Mr. Akira Izuka is therefore to be congratulated on having, in the course of his researches, brought to light no fewer than nine species belonging to these families. Three of the species thereof are new to science. He describes his captures in the Journal of the College of Science of the Imperial University of Tokio (vol. xxxvi., art. 5).

ACCORDING to Dr. J. H. Vernhout, in the July issue of *Zoologische Mededeelingen* (the organ of the Natural History Museum of Leyden), the parasitic *Petricola pholadiformis*, one of the "Venus-shells," recently introduced into British waters with American oysters, has also appeared on the Dutch coast. In addition to cases he has already recorded he now adds to this list Flushing, Isle of Walcheren, eastern Schelde, Zandvoort, and Terschelling. The introduction of American oysters into British waters has not proved an unmixed blessing. For another parasitic mollusc, *Crepidula fornicata*, the "slipper-limpet," one of the Capulidæ, introduced inadvertently into the Whitstable oyster-beds has now become a pest. Furthermore, it is slowly spreading round the coast.

AMONG the factors of elimination in the "struggle for existence," one does not usually reckon hot springs. Yet these, too, play their part. This much is apparent from the Bulletin of the University of Colorado (vol. xv., No. 6), wherein Messrs. Ellis and Henderson give an account of the Amphibia and Reptilia of Colorado. In the hot springs near Buena Vista, at an elevation of 8500 ft., they found larvæ of the Columbian toad (*Bufo boreas*) in an overflow pool at 23° C. Following the stream back, toward the spring, the temperature of the water increased rapidly, but the young toads continued abundant until the water was at 34° C. Above this point few were seen, though one small specimen was taken from water at 45° C. This toad was swimming rapidly, as if endeavouring to reach cooler water. The pools of very hot water, they remark, were death-traps for *Bufo boreas,* and numerous other animals. From one such pool, the water of which was 54° C., three large specimens of this toad and several insects were taken, the flesh of all of them being thoroughly cooked. A list of animals and plants described as new, and a key to the Entomostraca of Colorado, make up the rest of this bulletin.

IN the issue of *Knowledge* for September there is a short paper on the hairs of rock plants by K. E. Styan, with illustrations. The glandular hairs of the Saxifrages are described, and those of *S. granulata* and *S. lingulata* are figured. The three types of hairs dealt with are the silky or woolly hairs of the Edelweiss, *Sedum arachnoideum,* etc.; the stellate hairs which form a felted covering to many leaves, as in Aubretias and Alyssums, and the glandular, which may occur alone or in conjunction with one of the other types. The hairs are mainly protective against atmospheric conditions, but the glandular hairs may in some cases serve to attract insects.

A BOTANICAL survey of some fields near Leicester is a useful contribution to field botany by Miss Measham, published in the Transactions of the Leicester Literary and Philosophical Society, vol. xix. The fields are mapped, and from a study of the grasses in particular it was found possible to group certain fields together according to their types of vegetation. Fields, for instance, characterised by *Lolium perenne* form one group, while those with *Rhinanthus crista-galli* in abundance are taken as the type of another group. As a preparation for a flora of Leicestershire and Rutland, the work should prove of value.

THE Transactions of the Botanical Society of Edinburgh (vol. xxvi., part iv.) are largely occupied by an important paper on *Primula obconica,* Hance, and its microforms by Prof. Bayley Balfour. The paper is illustrated by thirty-six plates reproduced from photographs of herbarium specimens. The familiar plant *P. obconica* was collected near Ichang in 1879, and was raised from seed sent by Charles Maries to Messrs. Veitch, of Chelsea, in 1880. The type-plant grows in meadow land, but many of its forms grow on rocks in the limestone gorges. The species is widely distributed in eastern Asia, and extends into Burmah and Bhutan, *P. listeri,* King, the East Himalayan species, is mainly a sylvestral form with ivy-shaped leaves and short flower-scapes, but is linked up to the typical round-leaved *P. obconica,* with its longer flower-scapes, by a series of intermediate forms. The variants are nearer to the *obconica* type than to *listeri.* Prof. Balfour places in this Obconico-Listeri section fourteen well-marked micro-species, four of which are of his own making. *P. sino-listeri,* a glabiescent form with acute-lobed small leaves and long scapes, was collected recently by Forrest in Yunnan, and may prove to be a plant of horticultural value. It lacks the irritant property of *P. obconica,* Hance.

THE Report of the Agricultural Department of St. Lucia for the year 1914–15 is a record of steady progress, especially in connection with the lime and coconut industries. The Government lime juice factory proves to be in a flourishing condition, and products of a high quality are being prepared, of which details are given. Useful work is being done by the staff of the department in collecting the grasses of the island, both native and naturalised, with a view to their correct determination and also in order to obtain definite particulars of their economic value. The determinations of those unknown locally have been made by Mr. Hitchcock, the agrostologist to the U.S. Department of Agriculture, and useful notes are given on the more important grasses and an analysis to show their comparative feeding value.

A RELIEF model of Wales has been constructed for the National Museum, Cardiff. An account of its construction, with a geographical description of several of the blocks, has been published by the museum ("Descriptive Handbook to the Relief Model of Wales," by W. E. Whitehouse). The whole model measures 12 ft. by 10 ft. 6 in., and is on a scale of 1 in. to a mile. The vertical scale is 1 in. to 2000 ft. The museum hopes shortly to issue copies of the various blocks of the model at as low a price as possible. Despite the care that has undoubtedly been used in its construction, it is questionable whether such a model is not inferior for teaching purposes to a good contoured map on the same scale. In accuracy of detail there can be no comparison.

NEWS from Sir Aurel Stein of his explorations in Central Asia is published in the *Geographical Journal* for October (vol. xlvi., No. 4). A despatch from the Ulughart Valley dated July 10, 1915, gives an account of last winter's work in the Turfan region, which included a detailed survey of the Turfan depression and of the Kuruk-tagh mountains. The Kuruk-tagh and the Tian-shan range were linked to the trigonometrical survey of India. From Turfan Sir Aurel Stein moved to Korla in the spring, and thence to Kashgar. Large and important archæological collections were made. In a further despatch from "Camp Kara-Chem," Pamirs, August 8, 1915, Sir Aurel Stein says he is proceeding westward to the Pamir source of the Oxus. This he proposes to follow through Wakhan to Khorok, and thence to visit Roshan, Darwaz, Karategin, and so to reach the railway at Bokhara. He hopes to reach Meshed in Persia in October, and after spending the winter in Seistan, to return to India in March.

THE number and variety of the fossil reptiles and amphibians discovered in the Karoo formation of South Africa are very remarkable. Several new genera and species are described by Mr. S. H. Haughton in the Annals of the South African Museum, vol. xii., part iii., just received. Besides a well-preserved Labyrinthodont skeleton and various remains of the usual mammal-like reptiles, there is an interesting skull from the Stormberg Beds bearing much resemblance to that of Ornithosuchus from the Triassic sandstones of Elgin, Scotland.

PART of the lower jaw of a hoofed mammal with teeth like those of the peculiar extinct hoofed mammals of South America has been found in the Lower Eocene of Wyoming, U.S.A., and is described under the name of Arctostylops by Dr. W. D. Matthew in the Bulletin of the American Museum of Natural History, vol. xxxiv., art. xiv. This unexpected discovery suggests that at the beginning of the Tertiary epoch there may have been a longer and closer connection between South and North America than has hitherto been supposed. Numerous other jaws from the same formation and locality in Wyoming are referred by Dr. Matthew to primitive lemurs and insectivores. They show that at the beginning of the Eocene period the lemurs, insectivores, and carnivores cannot be clearly distinguished by the teeth alone.

A BOUND volume of "Papers from the Geological Department, Glasgow University," for 1914, has been issued by Messrs. J. Maclehose and Sons, Glasgow, with the sanction of the University Court. It is proposed to continue this publication annually. The present volume consists of reprints, of differing sizes, of papers published in various journals, some of which have been already noticed in NATURE. It remains to be seen whether a paper will be more readily traced by this mode of reproduction than in its original habitat. If the work relating to the Glasgow district were thus brought together, a new serial might be welcome; but it may be doubted if researches on South Georgia or the desiccation of the earth will be looked for under the head of the University of Glasgow. The volume is a further proof of the activity of what has become, under Prof. J. W. Gregory's influence, one of the chief schools of geology in our islands.

THE Proceedings of the American Philosophical Society for July contains an important article by Prof. A. E. Kennelley and Mr. H. O. Taylor, of Harvard University, on the extent to which the various portions of a telephone diaphragm move during vibration. The diaphragms were circular, of about 5 cm. diameter, of steel or glass, and clamped at the outer edge. The motion was observed by means of a triangular mirror of a millimetre side, one corner of which was pressed lightly against the diaphragm by the torsion of a thin phosphor-bronze strip to which the opposite side of the mirror was attached. The diaphragm was set into vibration either by the sound waves from a series of organ pipes or by alternating electric currents sent round an electromagnet behind it. In almost all cases within the telephonic range of intensity and frequency the diaphragms vibrated in their fundamental mode with the maximum displacement at or near the centre; and the law of distribution of displacement over the rest of the surface closely approximating to the theory as given by Lord Rayleigh in his "Theory of Sound."

THE *Scientific American* for October 2 contains an article on "America as her Own Chemist," giving an account of the first National Exposition of Chemical Industries, which was held in the Grand Central Palace of New York City during the week of September 20. It is stated that this exhibition illustrates in a very striking manner the remarkable advance made in the production of chemicals and dyes in the United States since Germany has been commercially isolated and prevented from exporting. The exhibition included three branches: first, chemicals, ores, metals, drugs, paints, and similar manufactured goods; secondly, apparatus and equipment for chemical laboratories; and, thirdly, machinery and equipment for manufacturing chemists, the treatment of ores, etc. Some of the most striking examples of progress were to be found in the exhibits illustrating the utilisation of waste cherry pips, raisin seeds, and apricot kernels; the application of the osage orange wood of Texas and Oklahoma in place of foreign fustic, and the production of useful products of distillation from different hardwoods. The Petrocine colours, now being manufactured from waste products of petroleum, which are being investigated by the Bureau of Foreign and Domestic Commerce, formed a striking example of new adaptations. The exhibit of the Bureau of Standards was a prominent feature of the exhibition, not only in presenting the apparatus used in the laboratories of the bureau, but also examples of chemicals, metals, ores, and materials recently tested.

AN important study of the quality of platinum ware by Messrs. G. K. Burgess and P. D. Sale is found in No. 254 of the Scientific Papers of the United States Bureau of Standards. A simple thermo-electric method has been devised to determine the degree of purity of the platinum used in platinum vessels which does not mar the article tested; it gives data for the classification of platinum in terms of its equivalent iridium (or rhodium) content. Of 164 pieces of platinum ware tested, 26 per cent. contained less than 0·5 per cent. of iridium and 67 per cent. less than 2 per cent. of this metal. A method is described of ascertaining the loss on heating of platinum crucibles by means of a suitable electric furnace containing no heated metal parts. The loss of weight due to heating per 100 sq. cm. of crucible surface at 1200° ranged from 0·71 mgrm. to 2·69 mgrm. per hour, the smaller losses being for crucibles containing rhodium and the greater losses for crucibles containing iridium. Iron appears to diminish the loss on heating, but its presence is objectionable on account of the soluble oxide formed on the crucible surface. It seems to be possible from a thermo-electric and microscopic examination of a crucible to predict its probable loss of weight on heating within fairly close limits. Suggestions are offered concerning specifications of quality for the highest grade of platinum ware, including the substitution of rhodium for iridium as a stiffening

agent, and the total elimination of iron. The nature of the disintegration of platinum and its alloys is briefly discussed.

THE announcements of Messrs. Crosby Lockwood and Son include:—A translation of Prof. Klingenberg's Large Electric Power Stations, illustrated; Oil-Field Development, by A. Beeby Thompson; Air Screws: an Analytical Study in the Application of the Analogy of an Aerofoil having a Rectilinear Motion, by M. A. S. Riach; and new editions of Naval Architect's and Shipbuilder's Pocket Book of Formulæ, Rules, and Tables (with a section on Aeronautics), by C. Mackrow and L. Woollard; Mechanical Handling of Material, by G. F. Zimmer.

MESSRS. GEORGE ALLEN AND UNWIN, LTD., will publish shortly:—Table of Compound Interest and Antilogarithms, by J. J. Stuckey, and a translation, by Dr. E. L. Schaub, of Prof. W. Wundt's Elements of Folk Psychology: Outlines of a Psychological History of the Development of Mankind.

OUR ASTRONOMICAL COLUMN.

THE GREAT METEOR OF OCTOBER 5.—A large number of descriptions of this object has reached Mr. W. F. Denning as the result of an appeal for observations published in some of the leading journals of the west of England. Mr. Denning sends us the following summary of the observations:—The meteor appears to have been widely seen over the S.W. region of England, and there were many observers in South Wales. Most of the spectators first saw a brilliant illumination of the sky and landscape, and, looking up to ascertain the cause, the end of the meteor or the luminous streak it left was at once perceived. To many of the observers in Cornwall and Devon the position of the object was in the N. by E. sky, and the streak remained visible for periods varying between two and twenty minutes.

The light evolved from the fireball at the instant of its greatest outburst is said to have exceeded that of the full moon, but there are not many really accurate accounts of its path amongst the stars. At first the streak was projected like a glowing bar among the stars between the pointers in Ursa Major and the Pole star, but it quickly became contorted and curled up, either into a ring with appendages or into an irregular ellipse, expanding as time went on, and becoming fainter.

Using many of the best observations of the meteor for comparison, the height seems to have been from 82 to 55 miles from over Lampeter to Neath, South Wales. The length of the visible course was about 42 miles, and velocity about 35 miles per second. Radiant at $248^\circ+72^\circ$; but this feature is rather doubtful, and it is hoped that further observations of the flight may yet be acquired so that the position may be tested. The eastern side of the streak expanded so quickly and with a motion decidedly eastwards that its velocity must have been equivalent to about 90 miles per hour.

PROPER MOTIONS MEASURED BY THE BLINK-MICROSCOPE.—There can be no doubt that stereoscopic or quasi-stereoscopic methods are destined to become of very great importance in astronomical work. Thus at the Lowell Observatory, Lampland has employed Pulfrich's device, the blink-microscope, for detecting variables and asteroids; at Yerkes, Slocum has shown that it is equally well adapted for finding proper motions, and the instrument has been enthusiastically adopted at the Union Observatory, Johannesburg. The director, Mr. R. T. A. Innes, can even see this instrument with standard transparent charts replacing the unwieldy durchmusterung catalogues. Already many variable stars have been discovered by its use, asteroids have been successfully picked up, and a good beginning has now been made in its application to the question of proper motions. In Circular No. 25, Union Observatory, Mr. Innes and Mr. J. Vôute, an assistant from the Leyden Observatory, who has been working at the Cape, both describe methods by which the proper motions of a number of stars in the great ω Centauri cluster have been measured. The former not only *detects*, but also *measures* the displacements with the "blink," whilst Mr. Vôute only uses it to make the selection, and then proceeds to take differential micrometric measures. The plates employed (astrographic) had been taken separated by an interval of 23·85 years. Of the 2000 stars on the plate, 30 presented measurable displacements (motions exceeding an annual value of $0{\cdot}04''$–$0{\cdot}06''$), whilst for fifty others the indications were doubtful.

THE LIGHT-CURVE OF XX CYGNI.—Several recently published papers concerning stellar variability have possessed somewhat exceptional attraction, not only in the variety of methods exemplified, but chiefly in consequence of the notable astrophysical importance of the stellar bodies investigated. Another such memoir appears in the September number of the *Astrophysical Journal*, Dr. Harlow Shapley and Martha B. Shapley presenting an account of the employment of the latest methods of photographic actinometry in the study of the light curve of XX Cygni. Previous work indicated that this star was to be regarded as an abnormal Cepheid variable, exceptional not only by reason of its short period—the most rapid known—but also because it had been shown by Kron to present a greater amplitude of light-change visually than photographically. Employing the Mount Wilson 60-in. refractor on four nights, upwards of 300 photographs of the star on ordinary plates alternately with isochromatic plates with yellow screen were secured, providing the material for a photographic and photo-visual investigation of its fluctuating light. The results obtained show that the shape of the mean light-curve, and also its range, are both variable. The visual range does not exceed the photographic but apparently is somewhat smaller. It is concluded that the maxima, although occurring at regular intervals, are disturbances varying in character, the minimum being the sensibly constant condition of the star. The value of the colour index indicates an average spectrum of the F type rather than A as classified at Harvard.

ATMOSPHERIC EFFECTS OF KATHODE RAYS.—M. J. Maurer, of the Central Meteorological Bureau, Zurich, describes (No. 4813, *Astronomische Nachrichten*) for the first time what is possibly an atmospheric effect due to solar kathode rays. Having formed the opinion that times of exceptional solar activity would be especially favourable for decisive observations of a long-suspected phenomenon, arrangements were accordingly made with Prof. Wolfer, who supplied information regarding the rapid development of solar activity about the middle of last June. The result was that between 2 and 3 p.m. on June 16, with a blue sky, in addition to the water-vapour halo of 70°, there was also observed a distinct brown aureole having a maximum breadth of about 15°. Prof. Wolfer also noted that some optical effect, comparable with the interposition of a slight veil of vapour, had interfered with his solar observations. It is further pointed out that Prof. Barnard recorded an auroral display on the night of June 16.

RECENT EXCAVATIONS ON A PALÆOLITHIC SITE IN JERSEY.

DURING the past summer excavations on the Palæolithic site known as La Cotte at St. Brelade, in Jersey, have been pushed on vigorously. When the work for the year came to an end in 1914 a trench had been driven across the cave from the western to the eastern side-wall, a distance of about 40 ft. This trench was about 8 ft. from the entrance. The excavations undertaken this year had three objects in view: first, to extend the examination of the Palæolithic floor along the western side-wall, of which 25 ft. in an inward direction had been uncovered in 1911, and if possible reach the hitherto undetermined back-wall; secondly, to clear the entrance of the cave along its whole breadth by removing the barrier of talus, about 25 ft. high, on the outer side of the trench; and lastly, on the inner side of the clearing thus made, to push along the eastern side-wall.

The work of excavation is being carried on by the Société Jersiaise, with the assistance of a committee of the British Association of which Dr. R. R. Marett is chairman. So much of the season's work as had been completed by the end of July was embodied in a report presented to the British Association at the Manchester meeting; but at that time not one-half of the season's work was over. Before describing the later results, it will be convenient to give a brief summary of what had already been done for those who may not have seen the report. The opening up of the Palæolithic floor along the western wall was carried forward a further 5 ft., worked flints being found sparsely at about 2 to 4 ft. above bench-mark. The cave was cleared across its entire front. The central part proved sterile, but a richly implementiferous bed, reaching from floor level to a height of 12 ft., was found under a ledge projecting some 12 ft. along the eastern side-wall. The finds, in addition to worked flints, included a large number of cores and hammer stones. There was also a great deal of bone in fair condition, one piece being apparently the knuckle-bone of a mammoth. A specially fine set of "hemi-Solutrian" implements occurred along the top of this bed. The working under the eastern wall was pushed forward for a distance of 27 ft., and revealed a quantity of burnt bone, indicating a former hearth. Flint was plentiful but of coarse pattern.

This was the extent of the work which had been carried out at the end of July. But by that time the roof of the cave, which consisted of masses of detached blocks, weighing anything up to ten or twelve tons, held in place by clay, had become unsafe. By dynamite and other means, however, all loose blocks, amounting to many tons, were removed, and the cave made reasonably safe after a fortnight's hard work. Excavations were then continued along the western side-wall for a further distance of 6 ft., when a projecting shelf of live rock was reached. On investigation it appeared that this was not the end of the cave. The shelf was undercut by a cavity penetrating inward at an angle of 45°. Here among other implements was found one of the most perfect of Mousterian "points" hitherto obtained on the site.

The working across the front of the cave proved rich in implements, but only up to the line corresponding to the line of the roof; beyond that it yielded nothing. The clearing of the *débris* on the inner side of the trench was begun and carried to a depth of about 30 ft. from the entrance right across the breadth of the cave. The breccia in the centre proved as rich in implements as the side-wall workings. The bone was in good condition, and included a magnificent tooth of a prehistoric elephant (? Antiquus) virtually intact. The implements for the most part were of a coarse type, but finer types occurred among them.

So much for the work of the month of August. It was proposed to carry on excavations throughout September in the hope of reaching the back wall of the cave. It was realised, however, that the work of clearing the undercutting on the western side was a danger. It had cleared away the support of a column of loose rock-rubbish, some 30 or 40 ft. thick, which had descended on the cave through a more or less vertical funnel. After two days' work, which proved remarkably rich in finds, the roof of the cave collapsed. Careful watch had been kept and no one was hurt, though warning was short—only a matter of minutes. About 1000 sq. ft. of floor had been opened up, but these workings are now completely buried under *débris*. As further falls are expected, work has been closed for the year.

Inspection of the chimney, the sides of which are now revealed, shows that another 20 ft. would have reached the cliff wall. It is probable, therefore, that the line of least resistance when work begins again will be to attack the cave from the back. In the meantime, the members of the Société Jersiaise and of the committee in charge of the exploration are busily engaged in sorting and classifying the finds. That this is a work of some magnitude will be gathered from the fact that in the past season some 3000 shaped implements, besides much workshop refuse and bone, have been taken from the site. Both in the number and the character of the finds it has proved one of the richest Palæolithic sites in Europe.

E. N. FALLAIZE.

THE LIGHTING OF FACTORIES AND WORKSHOPS.[1]

AT the present time, when so many factories are working at high pressure on Government contracts, the condition of workers well deserves scientific study. This point is emphasised by the recent appointment by the Minister of Munitions of War, with the concurrence of the Home Secretary, of a committee "to inquire and advise on questions of industrial fatigue, hours of labour, and other matters affecting the health and physical efficiency of workers in munition factories and workshops."

One matter of considerable importance in the factory—the matter of lighting—has just been dealt with in the First Report of the Departmental Committee appointed by the Home Secretary in 1913. The inquiry demanded special methods of investigation, and the committee has carried out a considerable amount of work. Evidence has been received from fifty witnesses, including inspectors of factories and representatives of various trade associations and scientific and technical societies. Eighty-five works in the chief industrial centres have been visited, and about 4000 measurements of illumination carried out. A series of experiments bearing on the standards of illumination required for various purposes was carried out at the National Physical Laboratory.

Inquiries were also made, through the Foreign Office, into the legislation relating to lighting in all the chief European countries and the United States, and the results are published in an appendix. In the United Kingdom no general provisions in regard to lighting (analogous to those regarding heating and ventilation) occur in the Factory Acts, although adequate lighting is required, in general terms, in underground bakehouses and in certain dangerous

[1] First Report of the Departmental Committee on Lighting in Factories and Workshops. Vol. i., Report and Appendices (Cd. 8000); Vol. ii., Minutes of Evidence, etc. (Cd. 8001). (London: H.M.S.O. and Wyman and Sons.) Vol. i., 11*d.*; Vol. ii., 1*s.* 7*d.*

trades. On the other hand, the codes of all the chief European countries, the United States, and India contain provisions requiring adequate lighting in factories.

The results of bad lighting have been studied in detail. A statistical inquiry into the number of accidents in various industries in each month of the year points to the conclusion that inadequate lighting is a contributory cause of accidents; it is significant that in mines the number of fatal accidents in surface work is greater in the winter when there is less daylight available, and the "accident rate" in most industries studied is considerably greater by artificial than by natural illumination. The evidence of witnesses and the statements of the Accident Offices Association, which embraces most of the insurance companies interested in the Workman's Compensation Act, supports this view. Specific instances are quoted of the effect of improved lighting in increasing the output and quality of work, and there is a general impression that unsatisfactory lighting is, in various ways, prejudicial to health.

The committee recommends that:—

(1) There should be a statutory provision:—

(*a*) Requiring adequate and suitable lighting in general terms in every part of a factory and workshop, and

(*b*) Giving power to the Secretary of State to make Orders defining adequate and suitable illumination for factories and workshops or for any parts thereof or for any processes carried on therein.

It is pointed out that "adequate lighting" should comply with the following requirements:—

(*a*) Adequacy.

(*b*) A reasonable degree of constancy and uniformity of illumination over the necessary area of work.

(*c*) The placing or shading of lamps so that the light from them does not fall directly in the eyes of an operator when engaged on his work, or when looking horizontally across the workroom.

(*d*) The placing of lights so as to avoid the casting of extraneous shadows on the work.

Certain recommendations are also made regarding the amount of illumination necessary in the working areas of factories, in foundries, dangerous parts of ways and open spaces, etc., and there is a special recommendation providing for exemption in special cases. These values, which range from 0·05–0·4 ft.-candle, are prescribed in the interests of safety and convenience, and without prejudice to the special illumination required for the carrying on of work. At present the committee is not prepared to recommend standards of illumination for various classes of work which require further investigation.

In the appendices, the measurements of illumination in various classes of factories are tabulated in such a way as to show the average values existing, and it is shown that the above values, which are suggested as a practical legal minimum, impose no hardship. Many manufacturers would prefer to provide substantially higher values, and these recommendations would be mainly instrumental in improving the illumination in out-of-date factories which have lagged behind the general advance. Besides carrying out tests of the artificial lighting in factories in terms of foot-candles, the committee has also accumulated a considerable amount of information regarding the natural illumination. This is expressed in terms of the "daylight factor" (*i.e.* the relation between the illumination inside a workroom and the total unrestricted illumination out of doors). The experiments at the National Physical Laboratory illustrate the connection existing between the amount of illumination required and the character of the material illuminated, which may be expressed thus:—

Coefficient of reflection of material × illumination necessary = constant.

Other experiments bear on the relative merits of direct and indirect lighting for certain classes of work. The visibility of detail consisting of fabrics, embossed papers, engraved metal, etc., demands unidirectional illumination, and the ability to distinguish such detail is, for the same illumination, greater by direct than by indirect light.

An enterprising step in connection with this report is the issue of a short memorandum summarising its aims and conclusions, and pointing out the special interest attaching to the report at the present time, when so many factories are working overtime and preparations are being made for the period of the year when artificial lighting is mainly required.

THE TURQUOISE.[1]

DURING several years, whilst a curator in the United States National Museum, Dr. Pogue collected all the available information respecting this familiar gem-mineral, visiting for this purpose the principal museums and libraries of America and Europe. The result is an elaborate compilation with numerous footnotes giving references to the scattered literature of the subject. Being an exhaustive treatise on turquoise, although containing practically no original matter, it would have been more accessible and convenient for reference if it had been issued as a separate octavo volume, rather than being buried in the large quarto volumes of an academy publication.

The various aspects under which the subject is treated are indicated in the title. The section on geology contains a detailed account of the occurrence of the mineral at all its known localities, particularly those in Persia, the Sinai Peninsula, and the south-western portion of the United States. The States of New Mexico, Arizona, California, Nevada, and Colorado, where many ancient workings are known, have recently become important sources of the mineral, producing stones rivalling the Persian in quality. A useful table is given stating the enclosing rocks (mainly igneous rocks, and especially trachyte), the associated minerals (usually limonite, kaolin, and sericite), etc., for the more important turquoise occurrences. The mode or modes of origin of the mineral are discussed, and the general conclusion drawn that it has been formed by the percolation of surface waters through aluminous rocks containing apatite and disseminated copper minerals. An attempt is made to disentangle the confusion associated with the name "chalchihuitl" of the American aborigines. Although the early Spaniards confused several green stones under this name, it would appear that the Indians of the south-western States referred to turquoise, whilst in Mexico the material so-called was mainly jade. A detailed bibliography and a good index complete the work. The plates are, for the most part, devoted to representations of ancient ornaments set with turquoises. L. J. S.

PURPOSEFUL FORAMINIFERS.

MR. EDWARD HERON-ALLEN is to be congratulated on the interesting results which are rewarding his assiduous study of the Foraminifera. His latest contribution (*Phil. Trans.*, June, 1915) deals with the processes of reproduction and of shell-making. In addition to the production of zoospores observed

[1] "The Turquoise. A Study of its History, Mineralogy, Geology, Ethnology, Archæology, Mythology, Folklore, and Technology." By J. E. Pogue. Memoirs of the National Academy of Sciences, Washington, D.C., 1915, vol. xii., part ii., 3rd Memoir, pp. 162, 22 plates.

by Lister and others, some species exhibit viviparous reproduction and the budding-off of young individuals. The viviparous young are formed inside the parent shell and emerge by the dissolution of the base. The process demands a sacrifice of the whole of the protoplasm and of the internal septa, whereas in zoospore-production the shells of the young are formed outside the parent, from material derived from the surrounding medium, and not from the internal septa. Another method of multiplication is to bud-off a young individual from the shell-aperture of the parent. To this process and to the occasional (possibly fortuitous) mingling of the extruded protoplasm of two or more shells, is generally attributable what has been described as "plastogamy" in the Foraminifera.

In regard to shell-making, Mr. Heron-Allen has some remarkable evidence to submit of a quality which he calls "intelligence," or "an apparent development of purpose." The Foraminifer may select out of a large supply of possibilities one particular kind of material, such as sponge-spicules, minute flakes of mica, Echinoderm plates, and it may use this material in a purposive way. Thus in *Technitella legumen* "the whole shell wall consists of two distinct layers of spicules, an outer layer in which the spicules are all laid down with their long axes parallel to the long axis of the test, and an inner layer of spicules laid with their long axes at right angles to the outer layer, giving as close an approximation to the woof and warp of a textile fabric as is possible with a rigid non-flexible material such as sponge-spicules. It is obvious that by the crossing of these two layers the strength and resistance of the test to strain is enormously increased."

Or again, while *Marsipella cylindrica* forms a long and very friable tube of broken sponge-spicules, "it was left for *M. spiralis* to make the same great discovery as did the prehistoric genius who invented string—it has clearly realised that a twisted yarn is stronger than an untwisted wisp of fibre." The author maintains that "the Foraminifera exhibit the highest functions and the most 'intelligent behaviour' of which undifferentiated protoplasm has been observed to be capable."

MATHEMATICAL AND PHYSICAL SCIENCE AT THE BRITISH ASSOCIATION.

THE Section of Mathematical and Physical Science met under the presidency of Sir F. W. Dyson, whose address on the construction of the heavens appeared in NATURE of September 9.

Radio-active Elements and the Periodic Law.

Following the address, a discussion on radio-active elements and the periodic law took place. The opener, Prof. F. Soddy, explained that the discovery of a large number of radio-active disintegration products seemed at first difficult to reconcile with the periodic table of the elements; for it was clear that the existing gaps would not provide for more than a few of them. But it had been found that among them there were only three new separable elements—radium, polonium, and actinium; the others were isotopes of known elements, *i.e.*, they had identical chemical properties, although differing somewhat in atomic weight. The fundamental discovery, which brought order amongst these diverse products, was that when an α particle was expelled a shift of two places to the left in the table took place, whilst the expulsion of a β particle caused a shift of one place to the right. Since an α particle carries two positive charges, and a β particle one negative charge, this suggests that position in the periodic table is a function of the charge. Moseley's work has extended this by showing that it is true from end to end of the periodic table. Another fundamental fact is Rutherford's discovery of the nucleus of the atom, which was detected by experiments in scattering. We arrive at the conclusion that isotopes have the same *net* nuclear charge, though the gross number of positive and negative charges differs. Isotopes cannot be separated by chemical means, and hitherto diffusion methods have been unsuccessful. In view of the numerous isotopes of lead the question of the variability of the atomic weight of lead derived from different minerals becomes important; variations from 206·05 (uranium lead) to 207·67 (thorite lead) have been found. The new view of the periodic table is that it is a relation between chemical character and nuclear charge, not between character and mass; and it is possible now to state that there are exactly 92 elements up to uranium (counting isotopes as one element), of which 86 are known. We seem to be returning to the view of the Greeks and alchemists that elements are qualities, in contrast to the later view that elements are constituents.

Dr. N. Bohr pointed out that the dimensions of the nucleus are so small compared with the outer rings of electrons, that the nuclear constitution would have negligible effect on the electric field in these outer parts, only the net charge being important. Consequently, properties depending on the outer rings of electrons would be the same for all isotopes. In the case of spectral vibrations, there occurs a small term depending on the mass of the central nucleus, and accordingly we ought to look out for a small but perceptible difference between the spectra of two isotopes. Dr. F. A. Lindemann gave a theoretical argument to show that you could not have identical chemical *and* physical properties when the atomic weight differed. If the chemical properties were the same, certain physical properties must differ, and *vice versâ*. Mr. A. Fleck compared the effects of taking away charges from uranium, (*a*) by reduction (uranous salts), and (*b*) by disintegration (UrX salts). Dr. Whytlaw Gray described experiments on minute quantities of RaD, showing that it answered the chemical tests for lead. He thought it would not be difficult to observe its melting point directly. Sir E. Rutherford said that it was surprising how simply the whole system of thirty-four new products had been absorbed in the periodic table. In one case we have seven isotopes, all radio-active except one (Pb). Those which show radio-activity are distinguishable from one another by that property. Several references were made to the loss of Mr. H. G.-J. Moseley, killed at the Dardanelles, to whose researches this subject has owed so much.

The Order of Stellar Evolution.

On Thursday morning, Prof. A. Fowler opened a discussion on spectral classification of stars and the order of stellar evolution. He described the order of the types of stellar spectrum, which, according to the Draper notation, form the sequence O, B, A, F, G, K, M, and pointed out that this sequence has come to be regarded not merely as a convenient mode of description, but as actually representing successive stages of evolution. The spectra present striking evidence of a continuity extending from one end to the other of the sequence, and there are links connecting the earliest type, O, to the gaseous nebulæ. The temperatures of the stars decrease in the order of the sequence from upwards of 10,000° C. for the B stars to 3000° C. for the M stars, and at the same time the colour changes continuously from white to red. Additional evidence in support of the sequence

is obtained from laboratory researches; from types G to M, the stars show spectral lines characteristic of the "arc"; from B2 to F the "spark" lines are shown; and in the earliest divisions O to B1 the lines are for the most part unattainable in the laboratory, except by the most powerful electric discharge. These last may be described as "super-spark" stars. The evidence fully establishes a physical continuity corresponding to the Draper sequence. Prof. Fowler concluded by referring to the theory of Sir Norman Lockyer, and to Prof. Russell's hypothesis, which is closely akin to it. According to these, the stars fall into parallel series of ascending and descending temperature respectively, so that the hottest stars (types B and O) come midway in the order of evolution.

Sir Frank Dyson set forth the evidence, based on the observed luminosities and densities of the stars, which led Russell to the view that the red stars represent both the earliest and latest stages of evolution. It seems necessary to believe that some of the M stars are extremely diffused bodies, and others very dense. The Draper sequence gives the order of temperature; but the order of evolution is that of increasing density, not necessarily that of decreasing temperature. Prof. Eddington pointed out that the actual calculations of stellar density in particular cases compel us to admit that two stars having the densities respectively of water and of air can yet show the same type of spectrum; this seems to remove one of the chief objections brought against Russell's theory. The adoption of this theory would, however, play havoc with the regularity of many statistical results which have hitherto seemed orderly and intelligible. Father Cortie referred to the changes of a spectrum in a Nova, which seem to show that in these cases the nebular and type O spectra come, not before, but after the B and A stages. Prof. Nicholson and Mr. Merton discussed the nature of the Wolf-Rayet spectrum (type O). In his reply, Prof. Fowler pointed out a serious difficulty of Russell's hypothesis, that we have no celestial spectra which can be regarded as bridging the gap between primordial nebulous matter and the intensely bright giant stars of type M.

Thermionic Emission.

On Friday Prof. O. W. Richardson opened a discussion on thermionic emission. He said that he would confine his remarks to the emission of negative ions from hot bodies, which seemed to be an intrinsic property, whereas the emission of positive ions was not permanent and could be traced to impurities. The emission of negative ions increases rapidly with temperature according to the formula $C=AT^{\frac{1}{2}}e^{-b/T}$, where T is the absolute temperature. It was found, however, by H. A. Wilson and by Langmuir that the constants depend greatly on the experimental conditions. The temperature-law would follow theoretically from purely physical considerations. On the other hand, a similar law may be deduced if the effect is due to chemical action. In the experiments of Haber and Just the emission of electrons from alkali metals was observed under the action of water vapour and other agents. This is the only known case of the kind, and the distribution of energy among the emitted electrons suggests that it is something different from thermionic emission. On the question of the distribution of energy among the electrons during chemical action, Prof. Richardson had gained the impression from his experiments that it did not conform to Maxwell's law, but was more analogous to the laws governing the photoelectric effect; the facts of thermionic emission require Maxwell's law. As the best possible test between the physical and chemical theories, he had recently conducted experiments on a tungsten wire with special precautions against impurities; the emission was found to be much too great and persistent to be accounted for by residual gaseous impurities. He concluded that the action was not chemical, nor could it be a photoelectric action of the temperature radiation; and the physical theory seemed the most satisfactory.

Dr. F. A. Lindemann discussed the bearing of the experiments on the chain theory of electric conduction. Mr. E. Newbery criticised the use of tungsten in the crucial experiment on account of its great chemical activity at high temperature. Dr. J. A. Harker discussed the bearing of experiments on the electric arc under high pressure.

Miscellaneous Papers.

There was no subdivision of the Section this year, and the papers selected for reading were taken in full Section. Technical subjects were therefore avoided, and even the mathematical papers were such as would appeal to the members generally. Mr. G. H. Hardy greatly interested his audience with a paper on prime numbers. He gave an historical survey of the investigation of the distribution of primes, with particular reference to the theorem that the number of primes less than x approaches asymptotically to $x/\log x$ for large numbers. This theorem was first conjectured by Legendre, but was not proved until 1896. An explanation of the importance of the Riemann-ζ function in this connection was given. The paper is to be printed *in extenso* in the report. Prof. A. N. Whitehead, in a paper on space, time, and relativity, gave an account of the philosophical difficulties connected with space and time so far as they concern mathematicians. His remarkably simple method of arriving at the fundamental equations of the principle of relativity was especially valuable. Mr. A. A. Robb and Mr. H. R. Hassé took part in the discussion, the former explaining his method of logical development of the subject based on the idea of points arranged in "conical order."

Prof. W. H. Bragg's account of X-rays and crystal structure showed the power of the new methods of determining the arrangement of the atoms in a crystal. Instead of attempting to summarise this remarkable paper, we may refer the reader to Prof. Bragg's Bakerian lecture in the *Phil. Trans.* (vol. ccxv., p. 253), which covers similar ground. Prof. J. C. McClennan gave an account of his production of single-line spectra of cadmium and zinc, showing that the wave-lengths of the lines are connected with the ionisation potential by a relation depending on the quantum theory. Sir J. Larmor discussed the decomposition of the irregular vibrations constituting white light into regular trains of waves, when a grating or prism is used; for the prism, he gave an explanation based on the difference between wave-velocity and group-velocity in a dispersive medium.

Meteorology was represented by a paper by Mr. F. J. W. Whipple on the mechanism of cyclones, in which an account was given of the observed distribution and pressure at different heights, and the dynamical connection between the pressure-gradient and the inflow and outflow of air was discussed. In presenting the report of the committee on seismology, Prof. H. H. Turner stated that the work of plotting on a map the earthquake epicentres observed by Milne had now been completed. The epicentres were found especially on two great circles cutting at right angles. He referred also to improvements made in

the Milne seismograph by Messrs. J. J. Shaw and J. H. Burgess.

The meeting concluded on Friday afternoon with a very interesting address by Prof. Pierre Weiss on new views of magnetism, in which he described his researches on the part played by the magneton, or definite unit of magnetism, in the phenomena of iron, nickel, cobalt, and their alloys.

THE BRITISH ASSOCIATION.

SECTION K

BOTANY.

OPENING ADDRESS[1] BY PROF. W. H. LANG, F.R.S., PRESIDENT OF THE SECTION.

Phyletic and Causal Morphology.

I PROPOSE to deal with some aspects of the study of plant-morphology. In doing so I shall not accept any definition of morphology that would separate it artificially from other departments of botany. I regard the aim of plant-morphology as the study and scientific explanation of the form, structure, and development of plants. This abandons any sharp separation of morphology and physiology, and claims for morphology a wider scope than has been customary for the past fifty years. During this period the problem of morphology has been recognised as being "a purely historical one," "perfectly distinct from any of the questions with which physiology has to do," its aim being "to reconstruct the evolutionary tree." The limitation of the purpose of morphological study, expressed in these phrases from the admirable addresses delivered to this section by Dr. Scott and Prof. Bower some twenty years ago, was due to the influence of the theory of descent. I fully recognise the interest of the phyletic ideal, but am unable to regard it as the exclusive, or perhaps as the most important, object of morphological investigation. To accept the limitation of morphology to genealogical problems is inconsistent with the progress of this branch of study before the acceptance of the theory of descent, and leaves out many of the most important problems that were raised and studied by the earlier morphologists.

In the history of morphology, after it had ceased to be the handmaid of the systematic botany of the higher plants, we may broadly distinguish an idealistic period, a developmental period, and a phyletic period. The period of developmental morphology, the most fruitful and the most purely inductive in our science, was characterised by an intimate connection between morphological and physiological work. Among its contributions were studies of development or "growth histories" of whole plants and their members. These were carried out, in part at least, in order to investigate the nature of development, and such general problems found their expression at the close of the period in the "Allgemeine Morphologie" of Hofmeister. The "Origin of Species" took some years before it affected the methods and aims of botanical work. Then its effect on morphology was revolutionary, and, as in all revolutions, some of the best elements of the previous *régime* were temporarily obscured. This excessive influence of the theory of descent upon morphology did not come from Darwin himself, but from his apostle Haeckel, who gave a very precise expression to the idea of a genealogical grouping of animals and plants, illustrated by elaborate hypothetical phylogenetic trees. Such ideas rapidly dominated morphological work, and we find a special "phylogenetic method" advocated by Strasburger. The persistence of the phyletic period to the present time is shown, not only in the devotion of morphology to questions of relationship, but in the attempts made to base homologies upon descent only. Lankester's idea of homogeny can be traced to the influence of Haeckel, and nothing shows the consistency of phyletic morphology to its clear but somewhat narrow ideal so plainly as the repeated attempts to introduce into practice a sharp distinction between homogeny and homoplasy.

[1] Abridged by the author.

Prof. Bower, in his address last year and in other papers, has dealt illuminatingly with the aims and methods of phyletic morphology. I need only direct attention to some aspects of the present position of this, which bear on causal morphology. The goal of phyletic morphology has throughout been to construct the genealogical tree of the vegetable kingdom. In some ways this seems farther off than ever. Phyletic work has been its own critic, and the phylogeny of the genealogical tree, since that first very complete monophyletic one by Haeckel, affords a clear example of a reduction series. The most recent and trustworthy graphic representations of the inter-relationships of plants look more like a bundle of sticks than a tree. Consider for a moment our complete ignorance of the inter-relationships of the Algæ, Bryophyta, and Pteridophyta. Regarding the Algæ we have no direct evidence, but the comparative study of existing forms has suggested parallel developments along four or more main lines from different starting-points in a very simple unicellular ancestry. We have no clue, direct or indirect, to the ancestral forms of the Bryophyta, and it is an open question whether there may not be as many parallel series in this group as in the Algæ. The Pteridophyta seem a better case, for we have direct evidence from fossil plants as well as the comparison of living forms to assist us. Though palæobotany has added the Sphenophyllales to the existing groups of vascular cryptogams and has greatly enlarged our conceptions of the others, there is no proof of how the great groups are related to one another. As in the Bryophyta, they may represent several completely independent parallel lines. There is no evidence as to what sort of plants the Pteridophyta were derived from, and in particular none that relates them to any group of Bryophyta or Algæ. I do not want to labour the argument, but much the same can be said of the seed-plants, though there is considerable evidence and fairly general agreement as to some Gymnosperms having come from ancient Filicales. The progress of phyletic work has thus brought into relief the limitations of the possible results and the inherent difficulties. As pointed out by Prof. Bower, we can hope for detailed and definite results only in particularly favourable cases, like that of the Filicales.

The change of attitude shown in recent phyletic work towards "parallel developments in phyla which are believed to have been of distinct origin" is even more significant. Prof. Bower spoke of the prevalence of this as an "obstacle to success," and so it is if our aim is purely phyletic. In another way the demonstration of parallel developments constitutes a positive result of great value. Thus Prof. Bower's own work has led to the recognition of a number of series leading from the lower to the higher Filicales. By independent but parallel evolutionary paths, from diverse starting-points in the more ancient ferns, such similarity has been reached that systematists have placed the plants of distinct origin in the same genus. In these progressions a number of characters run more or less clearly parallel, so that the final result appears to be due "to a phyletic drift that may have affected similarly a plurality of lines of descent." This conclusion, based on detailed investigation,

appears to me to be of far-reaching importance. If a "phyletic drift" in the ferns has resulted in the independent and parallel origin of such characters as dictyostely, the mixed sorus, and the very definite type of sporangium with a vertical annulus and transverse dehiscence, the case for parallel developments in other groups is greatly strengthened. The interest shifts to the causes underlying such progressive changes as appear in parallel developments, and the problem becomes one of causal morphology rather than purely historical.

The study of parallel developments would, indeed, seem likely to throw more light on the morphology of plants than the changes traced in a pure phyletic line, for it leads us to seek for common causes, whether internal or external. We cease to be limited in our comparisons by actual relationship, or forbidden to elucidate the organisation in one group by that which has arisen independently in another. Similarly the prohibition against comparing the one generation in the life-cycle with the other falls to the ground, quite apart from any question of whether the alternation is homologous or antithetic. The methods of advance and the causal factors concerned become the important things, and if, for example, light is thrown on the organisation of the fern-plant by comparison with the gametophyte of the moss, so much the better. This, however, is frankly to abandon phylogeny as "the only real basis of morphological study," and with this any attempt to base homology on homogeny. Many of the homologies that exist between series of parallel development are what have been happily termed homologies of organisation; these are sometimes so close as to result in practical identity, at other times so distinct as to be evident homoplasies. The critical study of homologies of organisation over as wide an area as possible becomes of primary interest and importance.

Since about the beginning of the present century a change of attitude towards morphological problems has become more and more evident in several ways. It seems to be a phyletic drift affecting simultaneously a plurality of lines of thought. The increasing tendency to look upon problems of development and construction from a causal point of view is seen in the prominence given to what may be termed developmental physiology, and also in what Goebel has called organography. These deal with the same problems from different sides and neither formulates them as they appear to the morphologist. Together with genetics, they indicate the need of recognising what I prefer to call general or causal morphology.

The problems of causal morphology are not new, though most of them are still unsolved and are difficult to formulate, let alone to answer. As we have seen, they were recognised in the time of developmental morphology, though they have since been almost wholly neglected by morphologists. So far as they have been studied during the phyletic period, it has been from the physiological rather than the morphological side. Still, such problems force themselves upon the ordinary morphologist, and it is from his position that I venture to approach them. I willingly recognise, however, that causal morphology may also be regarded as a department of plant-physiology. In development, which is the essential of the problem, the distinction between morphology and physiology really disappears, even if this distinction can be usefully maintained in the study of the fully developed organism. We are brought up against a fact which is readily overlooked in these days of specialisation, that botany is the scientific study of plants.

General morphology agrees with physiology in its aim, being a causal explanation of the plant and not historical. Its problems would remain if the phyletic history were before us in full. In the present state of our ignorance, however, we need not be limited to a physico-chemical explanation of the plant. Modern physiology rightly aims at this so far as possible, but, while successful in some departments, has to adopt other methods of explanation and analysis in dealing with irritability. It is even more obvious that no physico-chemical explanation extends far enough to reach the problems of development and morphological construction. The morphologist must therefore take the complicated form and its genesis in development and strive for a morphological analysis of the developing plant. This is to attack the problem from the other side, and to work back from the phenomena of organisation toward concepts of the nature of the underlying substance.

It is to these questions of general morphology with a causal aim (for causal morphology, though convenient, is really too ambitious a name for anything we yet possess) that I wish to ask your attention. All we can do at first is to take up a new attitude towards our problems, and to gather here and there hints upon which new lines of attack may be based. This new attitude is, however, as I have pointed out, a very old one, and in adopting it we re-connect with the period of developmental morphology. Since the limited time at my disposal forbids adequate reference to historical details, and to the work and thought of many botanists in this field, let me in a word disclaim any originality in trying to express in relation to some morphological problems what seems to me the significant trend, in part deliberate and in part unconscious, of morphology at present. The methods available in causal morphology are the detailed study in selected plants of the normal development and its results, comparison over as wide an area as possible, with special attention to the essential correspondences (homologies of organisation) arrived at independently, the study of variations, mutations, and abnormalities in the light of their development, and ultimately critical experimental work. This will be evident in the following attempt to look at some old questions from the causal point of view. I shall take them as suggested by the fern, without confining my remarks to this. The fern presents all the main problems in the morphology of the vegetative organs of the higher plants, and what little I have to say regarding the further step to the seed-habit will come as a natural appendix to its consideration.

Individual Development.

Twice in its normal life-history the fern exhibits a process of development starting from the single cell and resulting in the one case in the prothallus and in the other in the fern-plant. For the present we may treat these two stages in the life-history as individuals, their development presenting the same general problems as a plant of, say, Fucus or Enteromorpha, where there is no alternation of generations. How is the morphologist to regard this process of individual development?

In the first place, we seem forced to regard the specific distinctness as holding for the germ as well as the resulting mature plant, however the relation between the germ-cell and the characters of the developed organism is to be explained. We start thus with a conception of specific substance, leaving it quite an open question on what the specific nature depends. This enables us to state the problem of development freed from all considerations of the ultimate uses of the developed structure. The course of development to the adult condition can be looked upon as the manifestation of the properties of the specific substance under certain conditions. This

decides our attitude as morphologists to the functions of the plant and to teleology. Function does not concern us except in so far as it is found to enter as a causal factor into the process of development. Similarly, until purpose can be shown to be effective as a causal factor it is merely an unfortunate expression for the result attained.

Let me remind you, also, that the individual plant, whether it be unicellular, cœnocytic, or multicellular, may behave as a whole at all stages of its development. We see this, for instance, in the germination of Œdogonium, in the germination and subsequent strengthening of the basal region in Fucus or Laminaria, in the moss-plant or fern-plant, or in a dicotyledonous tree. A system of relations is evident in the plant, expressed in the polarity and the mutual influences of the main axis and lateral branches, as well as in the influences exerted on the basal region by the distant growing parts. We thus recognise, in its most general form, the correlation of parts, a concept of proved value in botany.

To some the expression of the observed facts in this way may appear perilously mystical. I do not think so myself. It is true that the nature of the specific substance and of the system of relations is unknown to us, but it is regarded as a subject for scientific inquiry and further explanation. To recognise fully the complexity of the substance of the plant is not, however, a step towards neo-vitalism, but is perhaps our best safeguard against the dangers of this.

The wholeness of the individual, together with important phenomena of regeneration, has suggested the conclusion that something other than physico-chemical or mechanical laws are concerned in the development of the organism. To this something Driesch applies the name entelechy. Without discussing the vitalistic philosophy of the organism, or other modern phases of philosophic thought that treat life as an entity, it seems worth while to point out that they are based mainly on the consideration of animal development. It would be interesting to inquire into the difficulties that are met with in applying such views to plants, where regeneration in one form or another is the rule rather than the exception, and often does not lead to restitution of the individual. Causal morphology can recognise phenomena of development and of the individual, which are at present beyond physico-chemical explanation, and try to attack them by any methods of investigation that seem practicable, without begging the main question at the outset and then proceeding deductively. To assume any special inner director of development, be it entelechy or vital force, is to cut the knot that may ultimately be untied.

The previous experience of botany in the time of nature-philosophy may well make us cautious of solving our difficulties by the help of any new biological philosophy. On the other hand, co-operation between biology and philosophic thought is highly desirable. In this connection I should like to refer to an idea contained in Prof. Alexander's paper on the basis of realism. He suggests that there is only one matrix from which all qualities arise, and that (without introducing any fresh stuff of existence) the secondary qualities, life, and at a still higher level, mind, emerge by some grouping of the elements within the matrix. The development of this idea as it applies to life would appear to offer a real point of contact between inductive biological work and philosophy.

To return to our plant, its development, with increase in size and progressive complexity of external form and internal structure, must be considered. The power of continued development possessed by most plants and wanting in most animals makes comparison between the two kingdoms difficult. That there is no fundamental difference between the continued and the definitely limited types of embryogeny is, however, shown by plants themselves. The bryophyte sporogonium is a clear example of the latter, while the fern sporophyte is one of many examples of the former. A difference less commonly emphasised is that in the sporogonium (as in the higher animals) the later stages of development proceed by transformation of the whole of the embryo into the mature or adult condition; in the fern-plant the apical development results in successive additions of regions which then attain their mature structure by transformation of the meristematic tissue.

These distinctions are of some importance in considering the generalisation originally founded on animal development and known as the biogenetic law. That "the ontogeny is a concise and compressed recapitulation of the phylogeny" is essentially a phyletic conception. It has been more or less criticised and challenged by some distinguished zoologists, and has always been difficult to apply to plants. If we avoid being prejudiced by zoological theory and results, we do not find that the characters of the embryos of plants have given the key to doubtful questions of phylogeny. What help do they give us, for instance, in the algæ or the vascular cryptogams? The extension of the idea of recapitulation to the successively formed regions of the seedling plant requires critical examination; if admitted, it is at any rate something different from what the zoologist usually means by this. The facts—as shown, for instance, in a young fern-plant—are most interesting, but can perhaps be better looked at in another way. Development is accompanied by an increase in size of the successively formed leaves and portions of stem, and the process is often cumulative, going on more and more rapidly as the means increase until the adult proportions are attained. The same specific system of relations may thus find different expression in the developing plant as constructive materials accumulate. I do not want to imply that the question is merely a quantitative one; quality of material may be involved, or the explanation may lie still deeper. The point is that the progression is not a necessary one due to some recapitulative memory.

There are some other classes of facts, clearly cognate to normal individual development, that seem to require the causal explanation. I may mention three:—(1) Vegetatively produced plants (from bulbils, gemmæ, etc.) tend in their development to pass through stages in elaboration similar to young plants developing from a spore or zygote. The similarities are more striking the smaller the portion of material from which a start is made. (2) Branches may repeat the stages in ontogeny more or less completely also in relation to differences in the nutritive conditions. (3) In the course of continued development there may be a return to the simpler form and structure passed through on the way to the more complex. These cases of parallels to, or reversals of, the normal ontogenetic sequence suggest explanation on causal lines, but are difficulties in the way of phyletic recapitulation; the first two cases can be included under this, while the third seems definitely antagonistic. On the whole, it may be said that recapitulation cannot be accepted for plants without further evidence, and that preliminary inquiry disposes us to seek a deeper and more fruitful method of explaining the facts of development.

The development of most plant-individuals starts from a single cell, and when we compare mature

forms of various grades of complexity the unicellular condition is also our usual starting-point. What is not so generally recognised or emphasised is the importance of the filament as the primitive construction-form of most plants. I do not use the word primitive in a phyletic sense, nor in the sense of an ideal form, but to indicate a real stage in independent progressions underlying many homologies of organisation. I cannot develop this fully here, but wide comparison of independent lines of advance suggests that the main types of progress in complexity of the plant-body have involved the elaboration of the single filament with apical growth and with subordinated "branches." It is generally recognised that various groups of algæ show how a solid multicellular axis may come about, not only by the further partition of the segments of the apical cell, but by the congenital cortication of a central filament or the congenital condensation of the subordinated "branches" on to the central axis. The algæ further show the change from the dome-shaped apical cell of a filament to the sunken initial cell with two, three, or four sides. The central filament then only appears, if at all, as a subsequent differentiation in the tissue, and the segments serially cut off from the apical cell may or may not bear projecting hair-shoots or "leaves." The algæ thus attain in independent lines a construction corresponding to that of the plant in liverworts and mosses. In the various parallel series of Bryophyta the filament is not only more or less evident in the ontogeny, but may be regarded as the form underlying both thallus and shoot, between which on this view there is no fundamental distinction. The sporogonium also can be readily regarded as an elaborated filament. While the same interpretation of the fern-prothallus will readily be granted, to think of the fern-plant as the equivalent of an elaborated filament may appear far-fetched. So far from this being the case, I believe that it will be found helpful in understanding the essential morphology of the shoot. In a number of vascular cryptogams and seed-plants, there is actually a filamentous juvenile stage, the suspensor, while the growth by a single apical cell is essentially the same in the fern as in the moss and some algæ.

There follows from this a natural explanation of the growth by a single initial cell so commonly found in plants. The apical cell appears to be the one part of the massive plant-body (for instance, of Laurencia, a moss, or a fern) that persists as a filament; it is a filament one cell long. It may be replaced by a group of initial cells, as we see in some algæ, liverworts, and Pteridophyta, and this leads naturally to the small-celled meristems found in most Gymnosperms and Angiosperms. The filamentous condition is then wholly lost, though the system of relations and especially the polarity is maintained throughout all the changes in the apical meristem.

I feel confirmed in regarding the construction of the sporophyte in this fashion by the fact that it fits naturally with the conclusions resulting from the masterly comparative treatment of the embryology of the vascular cryptogams by Prof. Bower. These are (1) the primary importance of the longitudinal axis of the shoot, the position of the first root and the foot being variable; (2) the constancy of the position of the stem-apex near the centre of the epibasal half of the embryo; (3) the probability that embryos without suspensors have been derived from forms with suspensors, without any example of the converse change. These and other related facts seem to find their morphological explanation in the shoot of the sporophyte being the result of the elaboration of a filament.

The Construction of the Shoot.

The view to which we are thus led is that the uniaxial shoot is a complex whole, equivalent to the axial filament together with its congenitally associated subordinated "branches." This applies to the multicellular plant-bodies found in various independent lines of algæ and Bryophyta, whether they have definite projecting appendages of the nature of leaves or not. The discarding of the distinction between thallus and shoot, which in practice has proved an unsatisfactory one, is no great loss. Even taking the word in the narrower sense of a stem with distinct leaves, the shoots in algæ, liverworts, and mosses, though admittedly independent developments, exhibit an essential correspondence amounting to a homology of organisation. The resemblances are not analogies, for it is doubtful whether the "leaves" in the different cases correspond in function. The comparison of the shoot of the sporophyte of a vascular cryptogam with, for example, the shoot of the moss seems equally justifiable. It is only forbidden by strict phyletic morphology, which for our purpose has no jurisdiction. The general agreement as regards the leaf-arrangement between the ferns and the Bryophyta suggests that similar laws will be found to hold in the shoot of both gametophyte and sporophyte. Apart from plagiotropic shoots, there is a constructionally dorsiventral type of fern-rhizome. The leaves of this alternate as in the leafy liverworts, while the radial type of fern corresponds to the moss-shoot. It is significant that the early leaves of radially constructed ferns usually exhibit a divergence of $\frac{1}{3}$ in the seedling, passing higher up the stem into more complicated arrangements, and the same is the case in mosses. I must not enter into questions of phyllotaxy, but may remark on the hopefulness of attacking it from the study of the simpler shoots of algæ and Bryophyta rather than, as has usually been done, beginning with the flowering plants.

In some ferns (the striking example being Ceratopteris) the relation between the segmentation of the apical cell and leaf-production is as definite as in the moss, each segment giving rise to a leaf. This may hold more widely for ferns than is at present demonstrated, and the question deserves thorough re-investigation to ascertain the facts independently of any theoretical views. That the coincidence of the segmentation of the shoot expressed by the leaf-arrangement and the segmentation of an apical cell is not a necessary one is, however, clearly shown in other ferns, and is obvious in the case of shoots with a small-celled meristem. The two segmentations appear to be determined by some deeper system of relations, which may also be manifested in a cœnocytic plant-body.

In the complication of the uniaxial shoot introduced by branching also there seems to be an advantage in a wide area of comparison. The question most often discussed concerns dichotomous and monopodial branching. If the details of development are to be taken into consideration, the term "dichotomy" has usually been very loosely applied. Apparent dichotomy, the continuation of one shoot by two equally strong ones, is fairly common. But in most cases investigated in detail the branching seems to be really monopodial and the forking due to the equally strong development of a lateral branch close to the main apex, not to the division of the latter. In plants growing by a single initial cell almost the only case of strict dichotomy known is the classic one of Dictyota. The branching of the ferns has been the subject of numerous investigations, but there is a great lack of developmental data. Usually the branches stand in some definite relation to the leaves

of the shoot, behind, to one side, or on the leaf-base, itself, the most interesting but least common case being when the branch is in an axillary position. When the mature shoot only is considered, it is possible to argue for the derivation of monopodial branching from dichotomy or the converse. Even the facts obtainable from the mature plant, however, point to the dichotomous branching being a modification of the monopodial, the opposite view appearing to land us in difficulties regarding the morphology of the main shoot. It is unlikely that a dichotomy involving the division of the apical cell occurs in the fern-shoot, and comparison with the Bryophyta confirms the suspicion that the cases of dichotomy are only apparent.

In considering the construction of the shoot we are at present limited to comparison of the normal structure and development. The system of relations in the shoot of the fern, affecting in the first place the distribution of the leaves and secondly that of the branches, appears, however, to be of the same nature as in the independently evolved shoots of Bryophyta and algæ. A morphological analysis based on the simpler examples may lead on to the experimental investigation of the common construction. The relation that exists between the general construction and the vascular anatomy offers a special and more immediately hopeful problem. Here also, in considering the fern, we are assisted by homologies of organisation in other vascular cryptogams and in the more complex Bryophyta, though the algæ are of little help.

In few departments of botany has our knowledge increased so greatly and become so accurate as in that of vascular anatomy. The definiteness of the structures concerned and the fact that they have been almost as readily studied in fossil as in living plants has led to this. Not less important have been the clear concepts first of the bundle system and later of the stele under which the wealth of fact has been brought. Great progress has been made under the influence of phyletic morphology, and anatomy has adopted further conventions of its own and tended to treat the vascular system as if it had an almost independent existence in the plant. The chief method employed has been the comparative study of the mature regions, of necessity in the fossils and by choice in the case of existing plants. I do not, of course, mean to say that we are ignorant of the development of the vascular system, but the variety in it has not been adequately studied in the light of apical development. A gap in our knowledge usually comes between the apical meristem itself and the region with a developed vascular system. It is in this intermediate region that the real differentiation takes place, and the arrangement of the first vascular tracts is then modified by unequal extension of the various parts. The apical differentiation requires separate study for each grade of complexity of the vascular system, even in the same plant.

If we look at the vascular system, not as if it had an independent existence or from the phyletic point of view, but as a differentiation taking place within the body of the individual plant, we can inquire as to the causal factors in the process. A deeper insight into the nature of the stele may be obtained by regarding it as the resultant of a number of factors, as part of the manifestation of the system of relations in development. The first step towards this is the critical consideration of normal developing plants, but so long as the causal influences in the developing substance of a plant remain unchanged the resulting vascular structure will remain constant. Our hope of advance lies in the study of cases where these influences are modified. Herein lies the value of abnormalities, of natural experiments, and the results of experimental interference. Possible influences that have at various times been suggested are functional stimuli, the inductive influence of the older pre-formed parts on the developing region, and formative stimuli of unknown nature proceeding from the developing region. The functional stimuli do not come into play at the time of laying down the vascular tracts, though they may have importance in their maintenance later; the inductive influence of the anatomy of older regions is excluded in the first differentiation of the vascular system in an embryo; we are thus led to attach special importance to the detection of the action of formative stimuli proceeding from the young developing primordia. We have further to take external stimuli into account, though these must act by influencing the internal system of relations.

Time will not permit of reference to the scattered literature bearing on this subject, but it may make the reality of such formative stimuli a little clearer if I refer to some examples that have turned up in the course of my morphological work. In the case of the shoot, formative influences must act in the small apical region where we have the meristematic growing point with the primordia of the leaves. There is a presumption in favour of some sort of segmental construction of the meristem in relation to the leaves, whether this coincides with the cell-segmentation or not, and such a segmental construction is reflected in the vascular system. Can we in the first place distinguish any parts played by influences from the stem-apex and the developing leaves respectively? Unfortunately we know little or nothing of the anatomical relations in the rare cases of adventitious leaf-formation. We get a little insight into the respective influences of leaf and axis, however, when we compare shoots with well-developed leaves and those without leaves or with greatly reduced leaves; this may be done between distinct plants or between different regions of the same plant. It seems to emerge from such comparisons that, as regards the xylem at least, a central strand may be independent of influences from the leaves, while the latter may not only determine the leaf-traces connecting with the central strand, but may influence the periphery of this; the result is a cylinder of outer xylem continuous with the leaf-traces. This general conception is borne out by widely different plants, the correspondences between which are homologies of organisation. I may instance the stele of the Polytrichaceæ as analysed by Mr. and Mrs. Tansley, the stele of the rhizome and aerial shoots of the Psilotaceæ, of the Lycopods with larger or smaller leaves, and the stele of the ferns at various ages of the plant. The shoot of Isoetes, which is of the Lycopod type, but has relatively large leaves, shows the composite nature of the stelar xylem particularly clearly, and also suggests how the component influences are at work in the meristematic region of the stem bringing about the resultant structure.

Owing to the small size of the shoot-apex, it is difficult to induce deviations from the normal to show the respective parts played by the central axis and by the influences from the leaf-primordia. The reality of influences proceeding backwards from developing structures is better brought out when they may be present or absent, and for this lateral buds are of special interest. As a rule, the primary development of buds has proceeded far enough to determine the connecting vascular tracts, but in the case of the dormant axillary apices of Botrychium no influence has been exercised on the vascular structure of the main shoot. When, however, such a lateral apex is called into activity, it not only forms its own vascular system as it develops, but exerts an influence backwards through permanent tissue leading to the pro-

duction of a "branch-trace" connecting with the adaxial face of the subtending leaf-trace. In Helminthostachys a similar connection is established with the stele of the main stem, and the influence may extend to the whole periphery of the main stele, inducing a continued or secondary production of xylem both behind and before the place of insertion of the branch.

These constructions were, in a sense, called forth by experimental interference, since they occurred in plants the normal apical growth of which had been arrested. Plants of Osmunda are normally unbranched, and no indication of dormant lateral apices has ever been detected. I tried on young plants of *Osmunda regalis* the experiment of injuring or destroying the apex of the shoot, with the result that in a number of them branching was induced. The vascular relations exhibited considerable variety, but in some clear cases the branch was developed in an axillary position with regard to a leaf-primordium, and its vascular connection was with the adaxial face of the subtending trace in the same fashion as in Botrychium and in some species of Zygopteris. The disturbance of the normal growth had apparently brought out (in more or less irregular form) the system of relations governing the position of development of lateral branches. The result showed the correspondence with what is the normal condition in some Zygopterideæ. It has been said from the phyletic side, and on the whole rightly, that experiment cannot reconstruct history. In the light of Dr. Kidston and Professor Gwynne-Vaughan's conclusions as to the derivation of the Osmundaceæ from a Zygopterid ancestry, this induced branching of Osmunda might almost be cited as a partial exception to the statement.

These examples will suffice to indicate the justification for a change of attitude in the study of the vascular system. Looked at in this light, the stele appears not as a characteristic thing inherited as such, but as a complex resultant. The problem gains in interest, new questions (which are different from, though not antagonistic to, phyletic problems) can be put as to stelar structure, leaf-trace structure, the venation of leaves, etc. We see this if we glance at the progression in stelar structure that accompanies the development of the young fern. The phyletic explanation has been recapitulation. We have found reason to criticise the adequacy of this as applied to external form, and the same line of criticism applies to the stelar progression. In this also the early stages may be hurried over or absent, and, still more significant, the early type of stelar structure may recur, when the shoot has fallen upon evil days and approximated in size of stem and leaf-form to the seedling condition. From such points of view the vascular system offers problems in general or causal morphology not merely of great interest, but with some possibility of solution. Thus the parallel progressions from protostely to a medullated monostele, and from protostely to solenostely and dictyostely may be treated as problems in the expansion and condensation of a stelar structure, which is itself the resultant of a system of influences. Such parallel progressions are before us within the ferns and also in other groups of vascular cryptogams.

(Alternation of generations, the morphology of the seed, and the morphology of the embryo of seed-plants were then considered from the viewpoint of causal morphology.)

Conclusion.

I have touched on a number of large questions, any one of which demanded separate treatment. My concern has not, however, been with them individually, but as cognate problems justifying the deliberate adoption of a causal explanation as the aim of morphological work. I have confined myself to problems bearing on the development and self-construction of the individual, and tried to treat them so as to illustrate the causal attitude and possible lines of attack. Preliminary speculations on the questions considered can at best contain a germ of truth, and must be subsequently adjusted in the light of further facts. I have discussed these questions rather than the smaller modifications in individual development shown in metamorphosis, partly because the latter have of late years been treated from a causal point of view, and partly because I wished to consider questions that immediately affect us as working morphologists.

Did time allow, we should naturally be led to recognise the same change of attitude in biological science toward the problems of the origin of new forms. Questions of bud-variation and mutation are clearly akin to some of those considered, and the whole subject of genetics is a special attempt at a causal explanation of form and structure and the resulting functions. Close co-operation between the morphological analysis of the plant and the genetic analysis attained by the study of hybridisation is most desirable. It is especially desirable that both should deal with structure as well as with form, and in the light of individual development.

The causal factors which have determined and guided evolution can be naturally regarded as an extension of the same line of inquiry. The Darwinian theory, and especially the exposition of the principle of natural selection, was the greatest contribution ever made to the causal explanation of the organic world. Strangely enough, it led to a period of morphological work in which the causal aim was almost lost sight of. Why evolution has taken place in certain directions and not in others is a problem to the solution of which causal morphology will contribute. The probability of orthogenesis, both in the animal and vegetable kingdoms, is again coming into prominence, however it is to be explained. When we consider the renewed activity in this field it is well to remember that, just as is the case with causal morphological work, we are picking up a broken thread in the botanical web. Lastly, as if summing up all our difficulties in one, we have the problem of adaptation. In attacking it we must realise that use and purpose have often been assumed rather than proved. We may look to scientific ecological work to help us to estimate the usefulness or the selection value of various characters of the plant. On the other hand, causal morphology may throw light on whether the "adaptation" has not, in some cases at least, arisen before there was a "use" for it. The hopeful sign in the recent study of these greater morphological problems is that the difficulties are being more intensely realised, and that rapid solutions are justly suspect. The more the causal attitude is adopted in ordinary morphological work, the more hope there is of these larger questions being inductively studied rather than argued about.

The causal aim is essentially different from the historical one, but there is no opposition between causal and phyletic morphology. They are rather mutually helpful, for there has been an evolution, not of mature plants, but of specific substances exhibiting development. A deeper insight into the nature of ontogeny is thus bound to be of assistance to phyletic morphology, while the tested results of phyletic work afford most valuable guidance in general causal morphology, though this cannot accept any limitation to single lines of descent in its comparisons.

I have tried to bring before you the possibilities of causal morphology partly because the same attention

has never been given to it in this country as to other branches of botany, and partly because if morphology be conceived in this broader spirit it need not be said that it has no practical bearing. I should not regard it as a serious disability were the study of purely scientific interest only, but this is not the case. When, if ever, we penetrate into the secrets of organisation so far as to be able to modify the organism at will (and genetics has advanced in this direction), the practical possibilities become incalculable.

Probably all of us have reflected on what changes the war may bring to botanical work. It is impossible to forecast this, but I should like to emphasise what my predecessor said in his address last year as to pure science being the root from which applied science must spring. Though results may seem far off, we must not slacken, but redouble our efforts towards the soluti)n of the fundamental problems of the organism. This can be done without any antagonism between pure and applied botany; indeed, there is every advantage in conducting investigations on plants of economic importance. It would be well if every botanist made himself really familiar with some limited portion of applied botany, so as to be able to give useful assistance and advice at need. The stimulus to investigation would amply repay the time required. Even in continuing to devote ourselves to pure botany we cannot afford to waste time and energy in purposeless work. It is written in "Alice in Wonderland" that "no wise fish goes anywhere without a porpoise," and this might hang as a text in every research laboratory.

A plant is a very mysterious and wonderful thing, and our business as botanists is to try to understand and explain it as a whole and to avoid being bound by any conventional views of the moment. We have to think of the plant as at once a physico-chemical mechanism and as a living being; to avoid either treating it as something essentially different from non-living matter or forcibly explaining it by the physics and chemistry of to-day. It is an advantage of the study of causal morphology that it requires us to keep the line between these two crudities, a line that may some day lead us to a causal explanation of the developing plant and the beginnings of a single science of botany.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—The course of six advanced lectures on "Stelar Anatomy in Angiosperms," by Miss E. N. Thomas, University reader in botany, announced to begin at Bedford College on November 1, has been postponed until January next.

OXFORD.—On October 26 the honorary degree of D.Sc. was conferred on Mr. Guy A. K. Marshall, director of the Imperial Bureau of Entomology. The Public Orator, in presenting Mr. Marshall, spoke of the great services rendered by him to scientific entomology during his residence in South Africa, mentioning in especial his work on Coleoptera and Lepidoptera. He also referred in appreciative terms to the valuable researches being carried on under Mr. Marshall's direction in the recently established Imperial Bureau of Entomology.

In moving Congregation for the grant of a pension to Mr. Henry Walters, assistant for forty-five years in the Clarendon Laboratory, Prof. E. B. Elliott made a sympathetic reference to the retirement of Prof. R. B. Clifton, after fifty years of devoted service to the department of physics in the University.

PROF. A. H. WHITE has resigned the chair of pathology in the school of the Royal College of Surgeons in Ireland, after a tenure of seventeen years.

DR. MICHELL CLARKE will deliver the Bradshaw lecture at the Royal College of Physicians of London on November 2, taking as his subject "Nervous Affections of the Sixth and Seventh Decades of Life"; the FitzPatrick lectures will be given on November 4 and 9, by Dr. W. H. R. Rivers, on "Medicine, Magic, and Religion"; and the Goulstonian lectures by Dr. Gordon Holmes, on November 16, 18, and 23, on "Acute Spinal Lesions, with Special Reference to those of Warfare."

THE arrangements announced in the calendar of the University of Leeds for the current session follow the same general lines of previous years. They are subject to modification in the event of rearrangements being necessitated by circumstances arising in connection with the war. As has become usual in our more modern universities, great prominence is given to the work in applied science and technology. Students may graduate in science and take for their principal subject one of the following branches:—Mechanical, civil, electrical, mining, or gas engineering; fuel and metallurgy; agriculture; colour chemistry and dyeing; and the chemistry of leather manufacture. Similarly the needs of commerce have been recognised. Students in the department of economics and commerce may take a three years' course for the degree of Bachelor of Commerce, a two years' course for the diploma in commerce, or a one year's course for the diploma in social organisation and public service. Side by side with these courses, designed to meet the special needs of the area served by the University, are others covering completely the requirements of students in arts, science, law, medicine, and so on. Evening classes in many subjects have been arranged and university extension lectures are provided in a miscellany of subjects.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society, October 5.—Prof. S. J. Hickson, president, in the chair.—W. J. **Perry**: The relationship between the geographical distributions of megalithic monuments and ancient mines. The fact that the distribution of megalithic monuments coincides with the centres of ancient mining and coast-lines adjoining pearl-shell fisheries suggests a genetic relationship between the two kinds of activities. The megalithic monuments that have been found in various places beyond the limits of the ancient East are the tombs and temples of the mining camps of the settlements engaged in exploiting gold, silver, copper, tin, and precious stones. The search for pearl-shell led the Phœnicians, and their pupils, from the Red Sea and the Persian Gulf to India and Ceylon, to Indonesia and Japan, to the islands of the Pacific, and eventually to America; and in every spot where they settled to work the mines or collect pearl-shell they planted the germs of the Old World civilisation.

PARIS.

Academy of Sciences, October 18.—M. Ed. Perrier in the chair.—The President announced the deaths of Gaston Vasseur and Henri Fabre.—Louis **Fabry** and Henri **Blondel**: The identity of the new Comas Sola planet with 193 Ambrosie. This planet proves to be identical with that discovered in 1879 by M. Coggia.—J. **Dejust**: The use of a Venturi tube for the direct

measurement of the flow in a pipe. The main pipe is by-passed at a point on the tube and at the contracted portion of the Venturi, and an ordinary small water meter is placed in the by-pass. It is shown both by calculation and experiment that the ratio of the volumes of water flowing by the two paths is constant to within 1 per cent. for varying rates of flow, and hence that the small meter can be graduated to give the total volume of water flowing through the main pipe.—Albert **Colson**: The heats of saturation of some alkaline salts.—Maurice **Drapier**: The application of cryoscopy to chemical analysis.—Em. **Bourquelot** and A. **Aubry**: The activity, in the course of the biochemical synthesis of the β-glucosides by β-glucosidase, of the other ferments which accompany it in the emulsin.

WASHINGTON, D.C.

National Academy of Sciences (Proceedings, No. 10, vol. i.).—G. G. **MacCurdy**: The octopus motive in ancient Chiriquian art. After discussing general features of animal motives in Chiriquian art, the octopus motive, which appears hitherto not to have been identified, is traced through a number of varying forms in vases, of which six are figured in cuts.—Rh. **Erdmann**: The life-cycle of *Trypanosoma brucei* in the rat and in rat plasma. The method employed affords the means of following, outside the body of the host, the sequence of changes in the life of trypanosomes, and its use has shown dimorphic forms, latent or round, and crithidia-like forms in *Trypanosoma brucei* outside of the host.—P. W. **Bridgman**: The effect of pressure on polymorphic transitions. This note presents, in a compact form by means of diagrams, many of the essential facts concerning the effect of high hydrostatic pressure on the polymorphic transitions of thirty substances.—G. M. **Green**: Isothermally conjugate nets of space curves. A necessary and sufficient condition that a conjugate net of curves on a surface be isothermally conjugate is that at each point of the surface the pair of axis tangents, the pair of associate conjugate tangents, and the pair of anti-ray tangents be pairs of the same involution.—P. D. **Lamson**: The rôle of the liver in acute polycythæmia. There is in the body a mechanism for regulating the red corpuscle content of the blood; this mechanism is under nervous control, responding to nervous, chemical, and emotional stimuli; the adrenal glands play a part in this mechanism, and the liver is the seat of the changes which increase the number of red cells, partly by a reduction in plasma volume, and partly by bringing cells into the circulation which are not normally present.—D. A. **MacInnes**: The potentials at the junctions of salt solutions. The author directs attention to the fact that the liquid junction potential E_L of a concentration-cell of the type

$$Ag + AgCl, KCl(C_1), KCl(C_2), AgCl + Ag$$

can be derived from measurements of its electromotive force, E, and of the cation-transference number, n_c, with the aid of the equation $E_L/E = (2n_c - 1)/2n_c$. This equation involves only the assumption that the work attending the transfer from one concentration to the other of one equivalent of ion is the same for the cation as for the anion. The author substantiates this assumption by showing that this equation, when applied to the electromotive force data of Jahn, leads to nearly the same values of $E - E_L$ (which should equal the difference in the two electrode-potentials) whether the electrolyte be KCl, NaCl, or HCl.—R. G. **Aitken**: A statistical study of the visual double stars in the northern sky. At least one in every eighteen, on the average, of the stars as bright as 9·0 magnitude in the northern half of the sky is a double star visible with the 36-in. telescope. Close visual double stars are relatively more numerous in the Milky Way than elsewhere in the sky, and visual double stars as a rule revolve in relatively small orbits. Close visual double stars are rare among stars of either very early or very late spectral class.—E. B. **Babcock**: Walnut mutant investigations. The mutation takes place in female flowers only, and appears in the first generation after the mutation occurs, but on crossing with the species type it is completely recessive in the F_2 generation, and the nature of the mutation is such that only certain genetic factors are affected without having the chromosome number disturbed.—C. B. **Davenport** and H. S. **Conard**: Hereditary fragility of bone. Of a parent who early in life was affected with brittle bones at least half the children will be similarly affected, but if neither parent, though of affected stock, has shown the tendency then expectation is that none of the children will have brittle bones.

CAPE TOWN.

Royal Society of South Africa, September 15.—Dr. L. Péringuey, president, in the chair.—Ethel M. **Doidge**: South African Perisporiales: (1) Perisporiaceæ. The Perisporiaceæ and allied fungi are very plentiful in South Africa, especially in forest regions and in warm districts with a fairly plentiful rainfall. The specimens in the Union Mycological Herbarium are mostly from the Woodbush forests in the Zoutpansberg, from the Knysna, and from the coast regions of Natal; there is also a fair sprinkling from other parts of the coast and from Natal as far inland as Pietermaritzburg. The Middle and High Veld of the Transvaal are only represented by a single specimen, a species of Dimeriella collected at Bandolier Kop. All that is known of the South African Perisporiales up to the present is comprised in diagnoses and descriptions of fungi collected by Prof. MacOwan and Dr. J. Medley Wood, and in a few descriptions of fungi more recently collected and published in the *Annales Mycologici* and elsewhere. All the earlier work was done in the Grahamstown district and the coast region of Natal, so that a large part of the Union was left totally unexplored so far as this group was concerned.—Alex. **Brown**: The arrangement of successive convergents in order of accuracy. One of the most important uses of simple continued fractions is for the solution of the problem to find the fraction the denominator of which does not exceed a given integer, which shall most closely approximate to a given number commensurable or incommensurable. A practically complete solution was provided by Lagrange in 1769 in his paper, "Sur la Resolution des Equations Numériques" in the *Mémoires de l'Académie royale des Sciences et Belles-Lettres de Berlin*. His results give the fraction nearest in defect and the fraction nearest in excess satisfying the conditions. He does not, however, consider the question of deciding which of these two fractions is nearest in absolute value to the given number. The author gives a proof of the rule and a method of arranging the convergents in one set so as to show the nearest in defect, the nearest in excess, and the nearest in absolute value, satisfying the stated condition.—Alex. **Brown**: The use of a standard parabola for drawing diagrams of bending moment and of shear in a beam uniformly loaded. The important stresses in a uniform continuous beam are the shear and the bending moment; they are best shown in the form of graphs where length along the beam is taken as abscissa and the required function as ordinate.

SCIENCE AND NESCIENCE.

MUCH attention has been given recently in Parliament and the public Press to the subject of protective measures against Zeppelins and other hostile aircraft. The position of the matter suggests that we have here another instance of the result of neglect of scientific knowledge, and of the prevision which comes with it, in our national executive. For many years Germany has been perfecting the Zeppelin airship with the view of making it an effective weapon of war. Every failure of an airship during this period has been gleefully chronicled in our daily papers, but until Zeppelins appeared over Antwerp and rained down bombs upon the city, little serious attention was given to them by the lay Press. We should have supposed, however, that the executive officers of departments entrusted with the country's defence would be fully informed of the progress that was being made, and that practical provision would be made to meet the danger likely to arise.

It appears now that our confidence has been misplaced, and that only in recent months have scientific measures been instituted to protect the country from airship attack. It is not for us to suggest how such attacks may best be met, but we do think there might have been a more capable anticipation of them and adequate means devised to meet them. It is easy to conceive airships in the future having sufficient strength to withstand all ordinary weather, but for offensive operations of value they cannot avoid being in sight of the ground, and thus laying themselves open to attack. We trust, therefore, that the possibility of airships being able to survive the anti-aircraft gunnery of the immediate future is remote, provided that their range can be found.

We are not, however, concerned here with these technical matters so much as with the national characteristic of indifference to scientific plans of action, whether pertaining to operations during war or of industry in times of peace. So little attention is given to science in most schools and colleges that it is rare to find an administrative officer or leading writer or speaker able to make a clear distinction between it and magic. With a few exceptions, the men who control or influence the welfare of the nation have been trained in schools in which science and humanity are regarded as antithetic. We were reminded very definitely of this in the early days of the war, when German barbarisms were placed at the door of scientific education by many writers in the daily Press; and we were warned not to depart from the road of literary culture if we wished to maintain our national characteristics. Since then the need for science in connection with inventions and munitions of war has been seen, and scientific committees have been appointed for various national purposes; but their work cannot be used to the utmost until our executive officials also possess a knowledge of science.

The whole system by which men are selected for administrative posts, or other positions of influence, is archaic, and neglects the knowledge of scientific methods demanded by a modern State. It is time to understand that no man can now be considered to have received a liberal education unless he has some acquaintance with the principles and methods of science; and that works of Pasteur and Faraday should be as familiar to all as those of Victor Hugo and Tennyson. The training which ends in literary culture without science is just as incomplete as that which promotes scientific knowledge without the power of clear expression.

Judging from statements commonly made in newspapers—not only in daily papers, but also in weekly periodicals in which greater accuracy might reasonably be expected—few writers have any knowledge of natural objects and phenomena. It is scarcely too much to say that, omitting signed articles written by experts, few newspapers make any announcement relating to a scientific subject without committing a mistake. Either terms are wrongly used, or a matter of common knowledge among men of science is regarded as a remarkable discovery, or sensational claims are presented to the public as if they were established truths, though they await confirmation from the scientific world, and are mostly unworthy of serious consideration.

It may be too much to expect men of letters to possess an elementary knowledge of science, or to have any sympathy with scientific precision, but it is not unreasonable to ask for accuracy of description when they are dealing with natural facts or phenomena. They may reply that even Shakespeare was at fault in matters pertaining to natural history; but he, at any rate, reflected in his works the best knowledge of his time, which is more than can be said of most writers to-day. We are often told that men of science should cultivate the art of literary expression, but the stronger necessity for men of letters to have at least a nodding acquaintance with the out-

standing facts of natural knowledge is overlooked. A well-known writer has unkindly said, "The man of science appears to be the only man in the world who has something to say, and he is the only man who does not know how to say it." The retort invited by this remark is that the man of letters frequently has nothing to say, and he says it at great length. The first business of the man of science is to create new knowledge, and not necessarily to clothe his discoveries in a pleasing dress, though he may do so. The facts of science provide material upon which literary art may be exercised, but the two functions of exploration and fine expression are rarely found together.

The methods of accurate observation and cautious interpretation demanded of scientific investigators do not readily lend themselves to attractive description, and the results require more mental concentration to understand them than is usually demanded of a literary performance. A writer of romance can let his imagination have free play, but when natural occurrences enter into the story they should be presented accurately if the material is to be used rightly. Nothing is easier than to be deceived by appearances, or to accept an assertion without inquiring into its foundations. The scientific plan of asking for evidence, and of limiting statements to those for which good justification can be produced, is much more tiresome, yet it is the only way by which truth can be attained; and that, after all, is the highest aim.

Writers in the popular Press, and in technical papers also, frequently indulge in cheap sneers at what they call "scientific theory." In their minds the man of science lives in a world far removed from the realities of life, and knows little of material things or practical possibilities. Nothing could be more incorrect than this view. With the exception of pure mathematics and metaphysics, every branch of physical and natural science depends for its progress upon practical work in the laboratory or the field. No one appreciates the value of experimental work more than the man of science, and no one is more critical of scientific theory. Whenever a theory is put forward in scientific circles, it is always subjected to severe attack from people most competent to point out its weaknesses; and, in any case, it only survives until someone brings forward evidence which disproves it.

Whether the world recognises it or no, all its material advance has been achieved by men of science. In the arts of sculpture and architecture, in literature, in philosophy, the position gained by Greece two thousand years ago remains the standard of excellence for the moderns, whereas the last fifty years or so have seen more additions to natural knowledge than all the ages before them; and the result has been not only advance in material welfare and comfort, but also in intellectual outlook. The present era will not be remembered in future history for its art, its literature, or its drama, but for its science, by which it is placed pre-eminent above all others. Though this is undoubtedly the case, the public is still guided and taught chiefly by men who know little or nothing of scientific methods or modern learning. It is not surprising that under these conditions the nation has yet to learn how to derive the highest advantage from the great scientific forces at its disposal.

THE COMPLETE WORKS OF TYCHO BRAHE.

Tychonis Brahe Opera Omnia. Tomus II. Edidit I. L. E. Dreyer. Pp. 461. (Copenhagen: Nielsen and Lydiche, 1915.)

THE first volume of this sumptuous reprint of the complete works of Tycho Brahe was noticed in NATURE last April. There will be thirteen volumes in all, of which the second has now appeared, containing the first and second of the three parts of the *Progymnasmata.* This is a posthumous work, as although a large portion of it was printed at Hveen under Tycho's direction, it was not completed until 1602, the year after his death; Kepler saw it through the press, and added an appendix. It is a general treatise on astronomy, both observational and theoretical; it commences with a dedication to the Emperor Rudolph II., and the diploma that he granted to Tycho. A document follows that is of special interest to British readers; it is the "privilege" of copyright in Scotland for thirty years, granted to Tycho by James VI. on the occasion of his visit to Hveen in 1590, just after his marriage to Anne of Denmark. Two Latin epigrams that were sent to Tycho by James are also printed.

The motion of the sun is the first astronomical problem discussed. Tycho in the beginning followed his predecessors in assuming that the solar orbit round the earth is an eccentric circle, described with uniform motion. This assumption involves adopting an eccentricity of the orbit that is just twice the true value. Shortly before the close of his life, he and Kepler detected the error of this assumption; it was too late to alter the matter in the text, as the sheets had been struck off, but Kepler drew attention to this correction, and some similar ones, in the appendix which he added.

Tycho made a good determination of the length of the tropical year, his error being only 1 second. He also obtained a good value of the constant of precession, by comparison of his results with those of Hipparchus and Ptolemy; he was able to show that the large "trepidations" or fluctuations in this motion, that were previously believed to exist, were wholly illusory.

Tables of the sun are given in the volume, the data extending to the year 1800. The annual advance of the perigee is taken as 45″, the true value being 61″. A short table of astronomical refraction is given; Tycho was one of the first to investigate this correction; his value 34′ for the horizontal refraction agrees with modern authorities, but he gives 5″ instead of 57″ for the value at 45° altitude. The erroneous assumption of 3′ for the solar parallax vitiated the refractions that were based on solar observations. Tycho's instruments were capable of proving that the true value was much smaller, but it never occurred to him to suspect the accepted value.

The section on the moon is specially interesting, for Tycho added important facts to our knowledge of its motion. He was an independent discoverer of the "variation," even if we admit the doubtful claim of Abul Wefa to be the first discoverer; in any case his writings were unknown in Europe until long after Tycho's time. Tycho also discovered the important "annual equation," and drew attention to the "reduction" arising from the inclination of the moon's path to the ecliptic. The mean values for the parallax and semidiameter adopted by Tycho, 60′ 51″ and 17′ 0″ respectively, are both too great, and further from the truth than the values 58′ 25″ and 16′ 25″ previously adopted by Copernicus. The latter, however, adopted an eccentricity double the true value, and Tycho greatly improved this element. Lunar tables are given in the volume, and their use illustrated by calculations of the details of the eclipses of the sun and moon that occurred near the end of the year 1601.

The chapter on the determination of the coordinates of the fixed stars opens with an account of the methods previously employed for connecting their places with that of the sun. The moon had generally been employed as an intermediary, either when visible in daylight, or when eclipsed, it being obviously practicable to connect the longitude of the shadow on the moon with that of the sun. Tycho used Venus as an intermediary; he found it possible to observe it in daylight when at its greatest brilliancy; the fact of its parallax, semidiameter, and motion being much smaller than those of the moon were great advantages. His star observations are astonishingly good, considering that no optical aid was available in his day; for example, fifteen values of the right ascension of Alpha Arietis, made between 1582 and 1587, and reduced to the end of 1585, range from 26° 0′ 4″ to 26° 0′ 44″, the mean value being 26° 0′ 29″, only 19″ less than the value calculated from modern data. Such work compares favourably with some that was done after the invention of the telescope, and it must be remembered that Tycho was ignorant of the existence of nutation and aberration.

He selected Alpha Arietis as the "Lapis Angularis" of his celestial structure, its proximity to the vernal equinox rendering it convenient for this purpose. A short list of fundamental stars, mainly in the Zodiac, have their places determined with special care. Then is given a less accurate catalogue of the longitudes and latitudes of about 800 stars for the epoch 1600. This must have been a great boon to his contemporaries, as the existing star catalogues were very inaccurate. A hundred bright stars have their right ascension and declination given for 1600 and 1700.

The reprint follows the original closely in type and pagination, the illustrations being reproduced in facsimile. They include diagrams of the instruments, which claim the admiration of astronomers, as the source of the observations from which Kepler deduced the laws of planetary motion.

The work is enriched with some annotations by Dr. Dreyer, directing attention to slips and inaccuracies in Tycho's text, or giving further information on various matters of interest.

ANDREW C. D. CROMMELIN.

PLANT-BREEDING.

Plant-breeding. By Prof. L. H. Bailey. New edition, revised by Arthur W. Gilbert. Pp. xviii+474. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1915.) Price 8*s*. 6*d*. net.

THE new edition of Prof. Bailey's text-book of plant-breeding contains a good deal of fresh matter. The work first appeared in the time when no order had been perceived in the phenomena of variation or heredity, and chapters by Dr. Gilbert are introduced dealing with the recent discoveries. These sections of the book are well done so far as they go, but though various parts have been rewritten, signs of irregular growth remain, as is, indeed, in such cases unavoidable.

In his preface Prof. Bailey expresses with some frankness a regret that with the new knowledge the old simplicity of ignorance has been troubled,

and strict criticism would therefore be scarcely in place.

The book still serves what was doubtless its first purpose—to excite curiosity regarding the nature and origin of plant varieties and to suggest the enormous possibilities which still lie before the plant breeder. Special reference might have been made, in this connection, to tropical products. Few, for example, have yet realised what incalculable additions to the world's wealth can yet be made by simple means. Rubber trees, for instance, vary at least 200 per cent. in yield, and it is with amazement that a plant-breeder learns that the planters are content to sow, without regard to breeding or quality, trees which are to last many years. To a less degree this is true of cocoanuts and many other objects of tropical agriculture. The chapter on the vast progress made in the teaching and investigation of plant-breeding in the United States gives evidence that this neglect will not long continue. The practical hints might well be amplified. Nothing is said, for example, of the method of removing pollen by a water-jet, though this device was, by the way, an American invention. More curious is the silence on the subject of self-sterility, a phenomenon which, whether as an obstacle or a help, plays so large a part in the daily experience of every plant-breeder.

The author's theoretical views are occasionally novel. In particular, the statement is made that individuality in plants is something quite distinct from what it is in animals. This proposition might with value be developed in an essay elucidating some of the essential phenomena of variation, but it is by no means a self-evident truth, to say no more. From the long list of periodicals dealing more or less with the subject, the *Zeitschrift für Induktive Vererbungsund Abstammungslehre*, though by far the most important continental journal, has by some accident been omitted.

THE BRITISH RAINFALL ORGANISATION.

British Rainfall, 1914: on the Distribution of Rain in Space and Time over the British Isles during the year 1914. By Dr. H. R. Mill and C. Salter. 54th annual volume. Pp. 448. (London: E. Stanford, Ltd., 1915.) Price 10s.

THE volume contains the records of about 5500 observers in Great Britain and Ireland, and there are various articles associated with rainfall. A paper on isomeric rainfall maps of the British Isles was contributed by the director of the British Rainfall Organisation to the Royal Meteorological Society in November, 1914, and the present volume contains a summary of the paper with the monthly and seasonal maps. A frontispiece in colour shows the relation of the rainfall in 1914 to the average of 1875–1909. The distribution of rainfall in time is dealt with in various ways from the ordinary daily records. For the occurrence of rain days, droughts, and rain spells over the British Isles one hundred stations have been selected, distributed uniformly over the country. The number of rain days are given in a tabular form for each month, and graphically for the average 1892–1911 and for the year 1914.

The year may be regarded as one of average rainfall frequency in all parts of the country, with generally fewer rain days in the summer and more in the winter than in a normal year. Absolute and partial droughts are discussed; the former is represented by a period of more than fourteen consecutive days, no one of which is a rain day, while a partial drought is a period of more than twenty-eight consecutive days, the mean rainfall of which does not exceed 0·01 in. per day. A rain-spell is practically the antithesis of an absolute drought, and is a period of more than fourteen consecutive days, every one of which is a rain day; the number of rain-spells in 1914 compared with the average was slightly deficient. Monthly, yearly, and seasonal rainfalls are given in a tabular form and graphically; for the British Isles as a whole the rainfall in 1914 was 7 per cent. more than the average.

The Meteorological Office having introduced a new system of units for the official records of British meteorology, the British Rainfall Organisation has fallen into line, and has adopted the use of the millimetre as the unit for measuring the depth of rain. The annual total rainfall for all the stations is given both in millimetres and inches, and this addition has involved the widening of the page of publication. The difficulty as to a change in the definition of a rain day consequent on the use of the metric units has been postponed to next year, and no alteration in this respect has been introduced in the present volume.

Notwithstanding many difficulties arising directly and indirectly from the war, the rainfall work has been carried out in all its details, although the exigencies of the times have caused some reduction of staff, and naturally the income has dropped. Greater stress is expected next year, and a hope is expressed that the rainfall records, so essential to the good of the country, will not suffer. An effort is being made to augment the voluntary funds by the aid of which the work is carried on, but public funds are not at present available, and the Treasury has decided that in the circumstances no action can be taken,

so that the organisation has to continue to depend on its own limited resources.

The results secured are a great gain to numerous corporations, water boards, and others. The work was initiated by the late Mr. G. J. Symons more than fifty years ago, and year by year the labours of the British Rainfall Organisation have increased in value, whilst the results have become of the highest scientific importance to the country.

NEW BOOKS ON CHEMISTRY.

(1) *Chemistry of Familiar Things.* By S. S. Sadtler. Pp. xiii+320. (Philadelphia and London: J. B. Lippincott Co., 1915.) Price 7s. 6d. net.

(2) *First Course in Chemistry.* By Prof. W. McPherson and Prof. W. E. Henderson. Pp. x+416. (Boston and London: Ginn and Co., 1915.) Price 5s. 6d.

(3) *Laboratory Exercises arranged to accompany "First Course in Chemistry."* By Prof. W. McPherson and Prof. W. E. Henderson. Pp. ix+128. (Boston and London: Ginn and Co., 1915.) Price 2s.

(4) *Identification of Common Carbon Compounds.* By J. N. Rakshit. Pp. iii+222. (Calcutta: The Collegian Office, 1915.)

(1) THE author has attempted an important, though difficult, task, that of interesting the unscientific person in the achievements of chemical science. He has applied himself to it with evident zest. As he truly says, "chemistry can furnish interesting subject-matter for general consideration." The chapters follow one another in a rough, natural sequence and cover a wide field. So far as we have read, there seems to be no attempt to teach or explain general principles, but rather to convey information, and this is done in a didactic manner, which admits of neither hesitation nor question. Theories and facts are poured out with equal assurance, and a note of interrogation is rarely sounded. This is not the least defect. The style is poor and not always clear; the definitions are obscure and often inaccurate, and the text abounds in incorrect scientific and historical statements. We have picked out a score of examples, but they would fill half a column, and it seems scarcely worth while to reproduce them. It is a misfortune that a book so handsomely bound, so nicely got up and well illustrated, and upon which, no doubt, the author has expended much labour, should contain such poor stuff.

(2) The theoretical and the accompanying practical volume (3) on elementary chemistry are intended for the beginner who does not intend to pursue the subject very far, but desires such information as an educated person might be expected and, if we were not tied to tradition, ought to possess.

From this point of view the book appears to fulfil exactly the author's object. In fact, it might be used with advantage as a beginner's text-book, whatever later course he intended to pursue.

There is no attempt here to be popular at the expense of accuracy. The authors have set before themselves the task of giving a clear and logical account of the outstanding facts and theories of the science in a simple, attractive, and at the same time soundly conscientious manner.

Like many of the elementary chemistry books produced in the States, it is profusely illustrated with excellent photographs. There is much to be said in favour of such illustrations. They relieve the sober monotony of the letterpress and, provided the relief does not produce a mere picture-book, no harm can be done. But there is always this danger, and in the present case it has not been entirely circumvented. Is any useful purpose served by depicting three workmen spraying an orchard with a lime-sulphur spray, or the process of loading a block of sulphur on to a railway truck? Why is there no diagram or photograph of a sulphuric acid plant, which would be so much more instructive? These are minor defects and are heavily counterbalanced by the excellence of the text.

(3) The accompanying laboratory course contains a series of simple experimental exercises, carefully arranged and well chosen, to illustrate the theoretical points. The student is being constantly pulled up and a question thrust upon him. If he is a conscientious student he will try to answer it and so accustom himself gradually to the process of interrogating himself, which is the only intelligent way of studying practical chemistry.

(4) This little volume contains a carefully compiled list of common organic compounds, with an account of their properties and characteristic reactions, as well as a number of useful tables. It is intended as a laboratory guide to the identification of organic compounds, and in so far should afford considerable assistance to the student. There is no attempt at a scheme of systematic analysis of the compounds to be identified, but apparently a good deal of reliance is placed upon the melting-points, a list of substances being tabulated at the end in order of increasing melting-point. Whether this method of identification by melting-point is useful either

as a practical method of identification or as an intellectual exercise is open to question; we are inclined to think that it is neither the one nor the other, and that the table should only be consulted when the group character of the compound has been definitely ascertained.

The fact that the book is written by a native of Bengal and printed by a Calcutta firm explains the occasional lapses in English, which is by no means to the discredit of either publisher or author; but it does not excuse the far too numerous mistakes in the spelling of chemical names. It is unfortunate that the volume has not been read in proof by someone conversant with the language.

OUR BOOKSHELF.

The Callendar Steam Tables. By Prof. H. L. *Callendar.* Pp. 39. (London: Edward Arnold, 1915.) Price 3*s.* net.

IN his Royal Society paper in 1900 and in his article on Vaporisation in the "Encyclopædia Britannica" of 1902, Prof. Callendar showed the use of a simple empirical formula connecting the pressure, density, and temperature of steam. If his formula is correct, it is possible to tabulate all the properties of steam required in engineering calculations in such ways that the numbers are more consistent with one another than any hitherto published. Mollier, of Dresden, published tables and corresponding curves calculated by this method, and these were republished in England by Ewing in 1910. Messrs. Smith and Warren calculated and published tables which were discussed in NATURE of April 3, 1913. We then gave reasons for the suggestion that perhaps such experimental results as were available scarcely justified the use of the Callendar method, in spite of the fact that Prof. Callendar is undoubtedly the highest authority on this subject. He now says that these tables form part of a larger work entitled "Properties of Steam," in which the theory of steam and experimental methods of investigation are more fully discussed and illustrated.

For the present we may, perhaps, assume that, for moderate pressures and temperatures, these tables are more correct than any hitherto published, and if this is so their value to the steam engineer cannot be over-praised. They give pound Centigrade and also pound Fahrenheit units, with pressures in pounds per square inch, volumes in cubic feet per pound, as well as kilogram Centigrade units, with pressures in kilos per square cm. and volumes in cubic metres per kilo. Table II. is the most important; it gives volume, entropy, temperature, and total heat in terms of pressure. Tables IV., V., VI., and VII. give the total heat, volume, entropy, and Gibbs's potential of super-heated and super-saturated steam. The diagram which accompanies the tables has been arranged for interesting graphical calculation. From this description steam engineers will see that, in addition to what is due for his engine experiments in Montreal, they owe the author a second deep debt of gratitude. The gas and petrol engine engineers also owe him a large debt. We do not think that there is any case of an experimental physicist since Regnault's time doing even half as much service to engineering.

J. P.

The Star Pocket-book, or How to Find your Way at Night by the Stars. By R. Weatherhead. Second impression. Pp. 92. (London: Longmans, Green and Co., 1915.) Price 1*s.* net.

THIS little manual not only provides an easy means of becoming familiar with the chief constellations and individual stars, but also shows how this knowledge may be made practically useful in the determination of position and direction during night marches. The book contains several useful tables giving among other details the time of year when certain stars transit at midnight, the highest altitudes of stars in various latitudes, and pairs of bright stars which transit at the same time. These simul-transit pairs, when vertical, mark the meridian, and also serve as pointers to a celestial pole. The new issue of the book includes some additional notes on the use of the stars as direction and time finders; and it should be found particularly helpful to soldiers and scouts at the present time.

The Cambridge Pocket Diary, 1915–1916. Pp. xv+255. (Cambridge: At the University Press, 1915.) Price 1*s.* net.

READERS whose work is connected with schools and colleges will find the arrangement of this attractively produced pocket diary very convenient. Beginning in the middle of September, it enables one to start a new diary at the commencement of the academic year. The miscellaneous information provided is intended primarily for members of the University of Cambridge.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Manganese Ore Requirements of Germany.

IN a letter, under the above title, published in NATURE of October 14, Dr. Leigh Fermor dissents from the conclusion reached in my article of July 15 on munition metals that the enemy countries can produce sufficient manganese for their steel manufacture requirements without having recourse to imports, and gives it as his opinion that they are likely to be seriously hampered by a shortage of manganese ore as soon as their accumulated stocks have been used. His conclusions are as follows:—

"(*a*) That on the outbreak of war the Teutonic Powers had no great accumulated stocks of manganese ore, perhaps a maximum of 200,000 tons; (*b*) that, assuming war conditions necessitate a maintenance of the iron and steel industries of those two countries at

a peace standard, about 600,000 tons of ore a year must be obtained from fresh sources to replace imports in time of peace; (*c*) that, allowing that the Teutonic Powers might succeed in increasing their internal production by 100,000 tons, and obtain 50,000 tons of manganese ore from Turkey, if the Allied Fleets could prevent all manganese ore from outside from reaching Germany and Austria, these countries would be faced with a shortage of 250,000 tons of manganese ore in the first year of the war, and with a shortage of 450,000 tons per year afterwards, increased to 500,000 tons per annum once the Dardanelles are forced.

"The Germans will doubtless find means of dispensing with the use of manganese ore as much as possible, and they may devise methods of utilising the manganese silicate, rhodonite, of which they appear to possess a considerable quantity; but it seems inevitable that the shortage of manganese ore, once it is felt, will hamper seriously the German iron and steel industries."

Dr. Fermor's conclusions, if correct, would mean that the German production of iron and steel must have been seriously diminished in the first year of the war, and that this diminution will be very greatly accentuated in succeeding years. Before producing evidence on this point which will, I think, be found to be decisive as to the issue between Dr. Fermor and myself, I should like to explain the reasons for the conclusion with regard to manganese at which I arrived in my article of July 15.

That article dealt with ten munition metals, and it was not possible within its limits to give more than a concise survey of the evidence bearing on each particular metal. I may say, however, that the detailed evidence which is so clearly and ably presented by Dr. Fermor with regard to manganese was available to and was considered by me, and that, excluding for the moment his brief reference to manganiferous iron ore, if this were all the evidence which had to be taken into consideration, I should have drawn the same conclusion as he has done—*i.e.*, that the enemy countries, and in particular Germany, could not supply their manganese ore requirements from internal resources.[1] There is, however, another factor which appeared to me on examination to be not only important, but vital. Dr. Fermor has also considered it, but evidently dismissed it as unimportant when he writes:—"I must note that in making the above calculations I have excluded figures for manganiferous iron ores from both the German and the world's figures as confusing the issue." It is with this factor that I must deal, for I came to the conclusion that it was decisive.

Although Germany prior to the war was a large and regular importer of manganese ores, she was by no means insensible of the technical value of her own deposits of manganiferous iron ores as a source of supply of manganese for steel production. In support of this assertion, it will be sufficient if I quote the following sentence from an article by Dr. Scheffer, of Dortmund,[2] which, it will be observed, was published shortly before the outbreak of war:—"Die Mehrzahl der Arbeiten die sich mit Manganerzen und Deutschlands Versorgung mit diesem Rohstoff befasst, beschäftigen sich nur mit der Manganversorgung Deutschlands aus dem Ausland ohne dabei zu berücksichtigen dass zur Erzeugung einer Reihe manganhaltiger Roheisensorten auch Eisenerze mit einem entsprechend niedrigeren Mangangehalt verwendet werden können und dass diese manganhaltigen Eisenerze im Inlande in grossen Mengen gefördert werden."[3]

Germany's production of manganese and manganiferous iron ores for the years 1908–1911, taken from Scheffer's paper, is appended in the following table:—

—	190 Metric	1909 Metric tons	1910 Metric tons	1911 Metric tons
(*a*) Manganese ores (above 30 per cent. Mn) ...	392	474	166	177
(*b*) Manganiferous brown iron ores (30–12 per cent. Mn)...	279,611	266,685	266,825	288,049
(*c*) Manganiferous brown iron ores (< 12–2 per cent. Mn)..	2,274,702	2,393,479	2,634,451	2,791,923

The main source of the home supply is the Siegerland.

The figures show that while the output of manganese ores is infinitesimal, there has been a large and almost steady output of the higher grade manganiferous iron ore, and a decided increase in the very large production of low-grade ore, the total output being in 1911 more than 3,000,000 tons. Calculation of the manganese tonnages of (*b*) and (*c*) gives the following figures for 1911:—

		Tons
(*b*) Mean value of 21 per cent. Mn gives	...	60,490
(*c*) Mean value of 6 per cent.[4] Mn gives	...	167,515
Total	... ...	228,005

Taking now the German steel production in 1913, the figures are as follows:—

		Tons
Total steel produced ...	...	= 18,960,000[5]
Steel exported ...	... ...	= 4,300,000
Home consumption of steel ...		= 14,660,000

Assuming an average manganese percentage of 0·75 in the finished steel, this will absorb

		Tons
		109,942
Amount available ...	... ...	= 228,005
Excess ...	...	118,063

From this it is clear that the tonnage of manganese contained in the ore as mined is ***more than double that required to be present in the finished steel.*** The excess would be available for deoxidising the fluid steel if it could be applied in a suitable form. Even here, however, it would not all be lost, for in 1911 the German blast-furnaces smelted more than 662,000 tons of manganiferous slag from open-hearth and puddling furnaces. With these facts before me, I had to consider whether the German manganiferous iron ores could be made available for steel manufacture in

[1] I am much obliged to Dr. Fermor for his explanation of the figures of American production, which is perfectly correct, for the information he gives of the mineralogical composition of the Indian ores, and for pointing out my omission of the Brazilian manganese ores.

[2] *Stahl und Eisen*, July 23, 1914, pp. 1246–1254. Other articles are published in "Glückauf," 1913.

[3] In the above article ores containing more than 30 per cent. of manganese are regarded as "manganese ores," while those containing both iron and manganese, the latter being present to the extent of anything between 2 and 30 per cent., are regarded as manganiferous iron ores. They contain technical values both in iron and manganese. The mineralogical concept of manganese and manganiferous iron ores is different; but we are only concerned with the metallurgical use of the terms.

[4] This is rather less than the mean value, but the estimate is purposely made conservative.

[5] Dr. Fermor gives this as 19·29 million tons in his first table, but this is the total *iron* production.

place of the customary ferromanganese or silico-spiegel. It has to be borne in mind that whereas in peace time in any given case that particular process holds the field which happens to be the cheapest, this is not the dominating consideration in war. If a commodity is essential for war purposes, and if the raw materials are available, it must be produced, *whatever it costs.* This being so, it appeared to me that while considerable departures would have to be made from ordinary practice, there was no insuperable difficulty in the technical problem of smelting the manganiferous iron ores in such a way as to render them available for steel production. It would not be advisable at the present time to say what my reasons were for coming to this conclusion, but I think my view would be supported by steel metallurgists generally.

Germany, however, has another source of manganese, the mineral rhodonite, which corresponds when pure to $MnSiO_3$. From this can be produced various grades of manganese silicon alloys by reduction in the electric furnace, as the following analyses show [6] :—

	No. 1. Per cent.	No. 2. Per cent.	No. 3. Per cent.
Manganese	74·2	70·3	55·0
Silicon	24·1	24·6	24·1
Iron	0·77	3·8	19·0

These products have the advantage over ferromanganese of being low in carbon, and yet possess a strong deoxidising power. Their use is specially advantageous in incorporating both manganese and silicon in steel. I was not able to obtain any figures showing the extent to which Germany was manufacturing these alloys before the war, but it appeared to me to be very probable—indeed, almost certain—that a considerable production, for which preparation would have been made, was to be expected in war time. Taking these facts into consideration, the conclusion appeared to me to be warranted that the German miners and metallurgists would, under the stimulus of necessity, be able to render their country independent of the import of manganese ores, and I therefore placed manganese in the category of metals that Germany would be able to produce from internal resources.

Dr. Fermor has come to the opposite conclusion. Much the same view was stated, though even more strongly, by a writer in the *Times* early in the spring of this year, who predicted that, owing to deficiencies in manganese supply, the German steel industry would collapse in June, 1915. Fortunately, the issue between Dr. Fermor and myself can be settled by what is, after all, the most satisfactory method, viz., the appeal to facts. I will give them briefly. The source of my information is the "Statistik des Vereins Deutscher Eisen und Stahl Industrieller," published in *Stahl und Eisen* (August 5 and September 23, 1915). There is, in my opinion, no reason for regarding the figures as incorrect. They are published in the official technical organ of the German iron and steel industry. They contain evidence of the setback caused to that industry by the outbreak of war, evidence which is supplemented in an article by Dr. Schrödter frankly admitting the difficulties with which it has had to contend,[7] and they show that those difficulties have been successfully surmounted.

Statistics of production of the various types of steel in each district are given, and may be consulted by those interested. For my purpose, however, it is sufficient to quote the monthly output of cast iron and steel from the outbreak of war for a whole year :—

Month	Cast iron Metric tons	Steel Metric tons
August, 1914	586,661	567,610
September	580,087	660,615
October	729,822	900,227
November	788,956	892,814
December	854,186	928,294
January, 1915	874,133	963,790
February	803,623	946,191
March	938,438	1,098,311
April	938,679	1,012,334
May	985,968	1,044,107
June	989,877	1,080,786
July	1,047,503	1,138,478

These figures tell their own tale, and require but little comment. Confining our attention to steel production, the output for August, 1914, the first month of the war, was only 36 per cent. of the average yield in peace time—very little more than one-third. It appears to have taken the Germans only two months to overcome their technical difficulties, as is evident from the October figures, which represent an enormous increase over those of August—rather more than 50 per cent. Apart from slight fluctuations, the figures thereafter show a steady increase, until those of the last month of the war are more than double those of the first month, and represent a rate of production rather above 72 per cent. of the peace rate. There are no signs here of an expiring industry; on the contrary, I venture to think that an unprejudiced examination of the figures shows us that it has been getting month by month into a stronger position. It may be urged that a drop of 28 per cent. represents a not unimportant shortage. But I must point out that this is calculated on the total production in peace time, when, as in 1913, 22·6 per cent. was exported. This condition no longer holds. Subtracting this amount, we obtain a difference of only 5·4 per cent. between the peace and war figures of production; in a few months this will have vanished if war requirements demand it. I estimate that before the end of this year Germany will be producing steel at the rate of between 14,000,000 and 15,000,000 tons per annum, and that that rate can be increased if necessary.

The foregoing is an achievement to which I, for one, cannot refrain from paying my tribute of admiration, even though I ventured to predict it. It is in the fullest sense of the phrase an important technical success for German metallurgists. How has it been done? Dr. Schrödter will not say. What he does say is :—"Die Erzeugung unserer jetzt auf heimische Rohstoffe angewiesenen Eisenindustrie ist so gross dass sie nicht nur alle Anforderungen von Landheer und Flotte erfüllt, sondern auch die notwendigen laufenden Mengen an Eisen für Friedenszwecke und darüber hinaus bis zu einem gewissen Grade den Bedarf für unsere benachbarten neutralen Länder zu liefern vermag. Diese erfreulicher Tatsache ist offenkundig. Wie wir uns in unseren Rohstoffen decken ist unser und unserer Metallurgen Geheimnis das wir der verbündeten Welt unserer Feinde preiszugeben natürlich keinen Anlass haben."

I think, however, there can be little doubt that the utilisation of the German manganiferous iron ores supplies the answer.

Austria has also surmounted her technical difficulties in steel production.[8] Her output is very much

[6] Bureau of Mines, U.S.A., Bulletin 77, pp. 145-46.
[7] "Die Eisen industrie im ersten Kriegs Jahr," pp. 798-800.
[8] *Stahl und Eisen*, 1914, pp. 818-19.

smaller than that of Germany, but is still by no means unimportant. The figures are as follows:—

	Tons
Production between August 1, 1913, and May 31, 1914	=819,000
Production between August 1, 1914, and May 31, 1915	=727,500
Difference	91,500

Of this drop of 91,500 tons, no fewer than 49,700 tons occurred in the first month of the war, and the following figures show that her present rate of production is greater than in the corresponding months of 1914:—

	1914 Metric tons	1915 Metric tons
January	78,300 ...	79,100
February	80,000 ...	84,500
March	107,800 ...	110,500
April	94,100 ...	99,000
May	95,500 ...	80,800

(The diminution in May, 1915, was caused by the opening of hostilities between Italy and Austria.) I have quoted the Austrian figures (which do not include Hungarian production) because in the article by Dr. Kestranek, of Vienna, from which they are taken, there is a direct reference to manganese and steel production. It is as follows:—"Die Stahlwerke Oesterreichs vermöchten die volle Höhe ihrer normalen Erzeugung zu erreichen und zu erhalten, trotz der Knappheit mancher für die Stahlerzeugung notwendige Stoffe. Man lernte rasch mit dem Verfugbaren hauszuhalten, für das Ersetzbares Ersatz zu finden, und alle im Lande vorhandenen bisher unbeachteten oder nicht voll ausgenutzten Hilfsquellen zu erschliessen. So wurde Beispielsweise die für die Stahlerzeugung heute als unentbehrlich angesehene Legierung des Ferromangans, zu deren Erzeugung man fast ausschiesslich auf die Verwendung der kaukasischen Manganerze angewiesen schien, sichergestellt durch die ökonomischen Verbrauch der noch vorhandenen grossen Vorräte an fremdländischen Manganerzen und durch Heranziehung der *im Inlande befindlichen Lägerstätten von solchen Erzen.*"

It is clear from this that the Austrians had accumulated pre-war stocks of manganese ore, and that they have succeeded in utilising their native manganiferous ores.

To sum up. Unless the evidence I have brought forward is untrustworthy—and I see no reason to doubt the figures of production, which bear ample witness to the setback both to the German and the Austrian iron and steel industries caused by the outbreak of war, which was followed by a remarkable recovery in the case of Germany (only two months later), and which has been well maintained, and indeed improved upon, during the succeeding months—then the conclusion appears to me to be fully warranted that Germany has succeeded in rendering herself independent of external supplies of manganese. According to Dr. Schrödter she is, in addition to supplying her own needs, exporting steel to her neutral neighbours.

Austria has been aided by her stocks of imported manganese ore, but has also been successful in utilising her own deposits.

So far from the figures of production showing a decline, which would certainly have set in by now if the shortage of manganiferous ore predicted by Dr. Fermor were correct, they bear witness to a remarkable degree of vitality and expansion in German steel production.

I wish to acknowledge my great indebtedness to Mr. G. C. Lloyd, the secretary of the Iron and Steel Institute, for the help he has given me in obtaining the figures of German and Austrian steel production that I have quoted.

The Government Scheme for the Organisation and Development of Scientific and Industrial Research.

THE proposal to establish a permanent State-aided organisation for the promotion of scientific research, with a view to its applications to trade and industry, is a most hopeful sign of the times, and will be welcomed in principle by scientific workers generally. But, inasmuch as any such scheme necessarily implies a certain amount of State control and direction of scientific research, and, ultimately also, of the large body of scientific workers who will be brought within its ambit, there are certain important matters to be considered and settled in principle at the outset, if the scheme is to be as fruitful and successful as it ought to be. I venture, therefore, in the spirit of a friendly critic and well-wisher to the scheme, to submit to your readers the following paragraphs embodying some of the points which seem to me to need very careful consideration, in order that the freedom and interests of individual scientific workers shall be sufficiently safeguarded and conserved.

(1) In my opinion what is most needful in this country for the development of scientific research in relation to industry is a central fund for the subsidising of a *limited* number of important lines of investigation, initiated and carried out by scientific workers and technologists of repute, who are, or have been, sufficiently in touch with practical affairs as to have acquired at first-hand a real knowledge of industrial conditions and of the economic factors which will necessarily come into play in connection with any new development. Such proposals might be initiated either by individuals so qualified, or by any group or association of such individuals, and such persons should have a strong (if not a majority) representation upon any Advisory Council or Committee appointed either to select or recommend suitable subjects for investigation, or to advise in connection with the prosecution of any investigation so selected.

(2) The selection of a particular line of research should be governed by three considerations mainly:—

(*a*) Its importance and practicability as directly bearing either upon the development or revival of national industries, and particularly of those which, although producing essential commodities (*e.g.* synthetic dyes or optical glass), have through past neglect become localised abroad, or which may conceivably be threatened in the near future, or upon questions pertaining to the future better utilisation of national resources of raw materials (*e.g.* coal and its by-products).

(*b*) The probability of there being a successful issue of the investigation within a reasonable time.

(*c*) The fact that its inauguration and continuous successful prosecution would involve expenditure beyond the financial resources either of an individual investigator (even though he may be aided by grants from the existing research funds of scientific and technical societies), or of the institution in, or in connection with, which he may be working.

(3) Broadly speaking, there are three distinct classes of investigation which would come within the above category, namely:—

(*a*) Investigations with the object of establishing new or more accurate scientific data, or methods, involved in the design of industrial appliances or plant, or in the daily scientific control and supervision of important manufacturing processes.

(*b*) Investigations with the object of effecting some modifications in the details of an existing process whereby it shall become technically and commercially more efficient.

(*c*) Investigations with the object of converting a scientific discovery (or results which may be predicated from research in pure science) into a useful scientific invention.

(4) Whilst all the above three classes of research are, or should be, essential features in any organised scheme for the benefit of trade and industry, the third class is undoubtedly, not only the most important of all, but also the one which presents the greatest executive difficulties in procedure, and unless at the outset these difficulties are both clearly recognised and equitably met, the complete success of the scheme will be seriously jeopardised.

(5) It ought to be recognised in principle that an individual scientific investigator who may seek or obtain assistance from the central national research fund should be accorded the fullest credit and protection for the ideas which he may disclose, as also direct personal access (without having to invoke the aid or interest of some intermediary person or association) to the Advisory Council or Committee (or persons representing them) administering the fund. Furthermore, if the ideas or discoveries disclosed by him are deemed important and worthy of support, as likely to result in a useful invention, not only should the further investigation of the matter be entrusted to his unhampered direction, but also, in the event of such further investigation under his direction ultimately resulting in a useful invention, his rights and interests in the commercial results of such invention should be equitably provided for and ensured.

To the objection which may be made that the acceptance by a scientific worker of assistance from a public fund for the development of his ideas or discoveries implies forfeiture on his part of any pecuniary advantage which would otherwise accrue to him, it may be replied that a scientific worker ought not to be put into a worse position in regard to the development of his discoveries, merely because he is financially assisted by the State, than he would have been had he been financed privately. It is a just and necessary principle in the development of inventions, no matter whether such development is financed by the State or by some private person or syndicate, that the inventor *qua* inventor is as much entitled in equity to a reasonable interest in the commercial results of his ideas as is the financial power that he may invoke, and unless such principle is conceded at the outset in connection with the Government scheme, it will never attract, or be invoked by, the scientific inventor for the development of his ideas. In short, invention and discovery, being essentially "individualistic" products, cannot flourish or be fully developed on a "socialistic" basis; and in every State-aided scheme there lurks the socialistic danger.

(6) If the above principle be conceded, there are doubtless formidable difficulties in carrying it out. Thus, for instance, it will be necessary to provide that the communication of an idea or discovery of an individual or group of individual scientific workers to an Advisory Board must not merely be *confidential*, but shall also confer the same sort of *provisional protection* which the lodging of a provisional specification at the Patent Office now confers. In the second place, should the further State-aided investigation of the matter result in a useful invention, not only ought the resources of the British Patent Office to be placed freely at the disposal of the inventor for the adequate protection of his invention, but also steps would have to be taken to ensure the same protection in all important foreign countries. For unless this were done, foreign manufacturers and countries would reap the reward of British scientific invention financed by the British taxpayer, without having to pay so much as a single halfpenny by way of royalties to the British people, and Great Britain would for ever sacrifice a most fruitful source of "invisible exports" in the shape of "British inventions."

Moreover, it might easily happen that an idea or invention originating in Britain, under a Government scheme without due safeguards, might be freely imported into Germany, and through German sources be patented in other countries for the benefit of Germany; such things have happened in the past under the existing patent laws, and will happen all the more in future, if the new scheme does not fully protect British scientific inventions. There thus lurks in the new scheme the serious danger of its proving an instrument and organisation whereby British brains and capital will be exploited largely for the benefit of the foreigner, and whilst such danger may perhaps be minimised by wise foresight, it is inherent in the scheme, and it is difficult to see how it can be entirely eliminated.

(7) The foregoing considerations do not, of course, apply to the first of the three classes of investigations cited in section 3 hereof, but unless they are frankly recognised and fully met at the outset, the utility of the scheme in regard to the important third class of investigation will be nullified.

The above suggestions are offered as an individual expression of opinion, which is the outcome of the writer's experience in connection with the development of his own inventions, in the hope that the final scheme will be so framed and safeguarded, in the common interests both of scientific invention and of the British public, that it may be of the utmost benefit to all concerned.

WILLIAM A. BONE.

London, November 2.

Science in National Affairs.

WHILE the leading article in NATURE of October 21 under the above title must meet with general approval on the part of men of science, there are one or two remarks to which I feel it my duty to direct attention in the interest of science at the present time, so far as it appears to me.

The "Scheme for the Organisation and Development of Scientific and Industrial Research," as issued in a White Paper by the Board of Education, should be carefully considered by us all. I may say that there is very good reason to believe that the gentlemen named in the article in NATURE, Mr. Arthur Henderson, Sir A. Selby-Bigge, and Dr. H. F. Heath, although their chief interests may be in "other fields than those of science," are nevertheless sincerely desirous of improvement in the position of scientific research in this country. If this is so, it is surely our duty, as well as interest, as men of science, to assist so far as we possibly can in what is undoubtedly a new opportunity. There is no doubt that the administrative chairman, Sir Wm. M'Cormick, will gladly welcome suggestions made with the intention of helping the scheme.

I would point out that the Advisory Council, which has the control of the way in which money is to be spent, consists entirely, with the exception of the chairman above named, of well-known and honoured men of science. It may probably be found necessary to place on this Council representatives of biological

science, but this is a detail, and could be done at a later date.

Whatever may be our views as to a democratic constitution, it must be remembered that it exists, and nothing but obstruction is likely to result from throwing stones at it. It is to be feared that what feeling of opposition to science is present in the democratic mind is largely due to the arrogance apt to be shown by men of science. Skill and success in a particular branch of science alone do not warrant the demand that their possessor shall be regarded as capable of expressing opinions of value on any and all questions of public importance. The same may be said, of course, of any branch of learning. But it can scarcely be held that men of science, as such, have hitherto shown an especially great capacity for business or administrative ability; perhaps it may be because opportunity has been wanting.

We must also confess that ignorance of, or want of interest in, branches of knowledge outside their own domain is not exclusively confined to men of a literary or legal training. At the same time, it may, I think, be reasonably asserted that a wide outlook is more common amongst men of science than amongst other members of the community.

May I suggest that a more conciliatory attitude than that too often assumed with respect to what seem to be well-meant efforts on the part of Government Departments would be more to our interest and for the benefit of the nation? There is, no doubt, a very great deal yet to be done in connection with the position of science in the State. But we may do much in assisting those who are inclined to look with favour on our desires and demands, although it may be that too many of the positions of authority are filled by men lacking in appreciation of the meaning and aims of science. We have an opportunity of showing our value to the nation, and, if we use it well, greater duties and responsibilities will follow.

W. M. BAYLISS.

University College, London, October 23.

[WE do not doubt for a moment that the gentlemen mentioned by Prof. Bayliss take a sympathetic interest in the promotion of scientific research, but this can scarcely be regarded as specially enabling them to administer a scheme to promote the co-ordination of science and industry. What we particularly object to is the assumption, made in all Government offices, that men without scientific knowledge are alone capable of controlling scientific departments and committees. The executive officers of the Committee and Advisory Council on Scientific and Industrial Research represent only one illustration of a principle for which there is no substantial basis. Prof. Bayliss seems disposed to concede this principle: we are not. He suggests that men of science do not possess much business or administrative capacity: we do not accept this generalisation; and we hold that they could scarcely be less effective and less enterprising than administrators trained in unscientific schools. No one supposes that skill and success in science give authority to opinions expressed on other subjects, but neither does work in literary and legal fields create ability to deal with the practical problems of science and technology. Science has too long been content to occupy a subordinate position in the national executive; and the main object of our article was to assert its claims to a higher place.—ED. NATURE.]

A New X-Ray Technique.

THE remarkable therapeutic action of radiations with a range of wave-length from $3{\cdot}8\times10^{-5}$ cm. to $0{\cdot}99\times10^{-9}$ cm. is now generally known and recognised by the medical profession. Between the limits $\lambda=1{\cdot}72\times10^{-9}$ cm., the shortest wave emitted by a Coolidge tube, and $\lambda=0{\cdot}99\times10^{-9}$ cm., the length of the waves of gamma rays from radium C, there is a gap which has so far defied all attempts at bridging.

Meanwhile, physico-physiological laboratories have their hands full with many problems concerning the action of the numerous radiations already available. Research work in this direction can only progress slowly; far more slowly, in fact, than investigations undertaken in perhaps any other branch of physics. But the prospect of final success, and in any case the task of alleviating sickness and pain, is so compelling that he who attacks this problem in the true spirit of science is unconscious of any sacrifice.

Now the various strong inducements presented to the physician by this new method of treatment have led to the hasty accumulation of a large number of facts and a mass of data which serve at the present time as the basis of modern X-ray technique. In the absence so far of any wide generalisation emanating from laboratory work, this necessary knowledge has been largely acquired by the elementary process of trial and error.

I wish, however, to refer here only to that part of the subject which relates to the treatment of deeply-seated tumours and to point out that so astonishing, both as regards action and inaction, are many of the results of treatment by this pleasant and painless means that it is very desirable to pursue the matter as systematically as possible. From the outset, the physician has met with the difficulty of administering a large dose of radiation to an internal region of the body without endangering the more superficial tissues. It has hitherto been usual, therefore, to make comparatively short exposures, taking care at the same time that the intervals between them be not too brief. In order to obviate this drawback the method of "crossfire" has been largely developed on the Continent, the patient being mapped out into several definite areas and the exposures made through several "ports of entry," with the rays always pointing towards the seat of disease.

It occurred, however, to the writer some months ago that by a suitable means of rotating a single X-ray tube and screening off with lead the rays from it, except a comparatively small pencil of them, it would be possible to bring to bear upon a deeply-seated region in the body a far greater amount of radiant energy in a given time than existed at the skin surface during treatment. Intensity of radiation is defined as the energy falling upon one square centimetre of receiving surface, and it is clear that if a conical beam of X-rays could be sent towards a diseased region so that the apex of the cone rested upon the neoplasm, the intensity of radiation there would be far greater than at the skin surface, where the area traversed by the rays is larger. But this would involve a source of rays consisting of a beam of large cross-section and the ability to concentrate it to a focus, the former condition being difficult to obtain and the latter impossible.

Nevertheless, since time enters into the question in the case of therapeutic action it is possible to approximate to the above conditions by the simple device of attaching the X-ray bulb to the circumference of a slowly revolving wheel of about 18 in. diameter, and with its axis pointing towards the diseased region. The screen is arranged to give a slanting beam that makes a convenient angle with the axis of rotation. Thus a hollow cone is swept out by the revolving pencil of rays, and it becomes possible to give a dose of radiation to a deeply-seated tumour ten or more times as great as that received by the skin. In this

way the exposure can therefore be safely made at least ten times longer than is usually possible by the ordinary method in general use and without damaging the superficial tissues.

It is to be noticed that the chief advantage of this plan lies in the fact that whereas at the apex of the cone swept out by the revolving beam the radiation is operative during the whole exposure, at the skin surface the pencil of rays only impinges upon a small area at any moment, always passing slowly on as the tube revolves so as to irradiate a large ring, section by section, of perhaps one inch in width.

Some rough experiments already made by the writer with a crude form of tube frame revolved by hand have given promising results. In spite of the fact that the source of radiation in a focus tube is practically a point, all rays being therefore divergent and their intensity falling off inversely as the square of the distance; in spite, too, of the absorption of some of the beam's energy as it traverses the tissues, it was found that the time-intensity factor could be made in this way considerably larger at the seat of the disease than at the skin surface.

The method is already being given a practical trial at the Cancer Hospital, London, and may prove later to be applicable also in treatment by radium.

Australian Photographs.

Readers of Nature, and especially members of the British Association, may be interested to know that I have received to-day (October 25), too late for incorporation in the "Overseas Camera in Australia," now being distributed to subscribers on behalf of the funds of the British Red Cross Society and Order of St. John, a remarkably fine series (300 or more) of photographs of features of general and scientific interest of New South Wales, presented by the Premier of this State through Mr. J. H. Maiden, the director of the Botanic Gardens, Sydney, and taken by the Government printer. The photographs are of interest to botanists, zoologists, foresters, agriculturists, geologists, miners, and astronomers. I shall be glad to supply lists or further particulars to anyone interested.

TRENCH "FROST-BITE."

During the winter campaign of 1914–15 a number of soldiers fighting in the trenches in Flanders became disabled from the effects of cold and wet on their feet. The condition is to be distinguished from true frost-bite, in which severe cold causes necrosis or death of the tissues; but though this may occur, it is infrequent in trench frost-bite, the characteristic symptoms of which are swelling, pain, and disturbance of sensation in the part affected. For this reason Delépine[1] suggests the name "frigorism" or "frigidism" for this condition, corresponding with "froidure," used by several French writers.

Three factors seem to be concerned in the causation of trench frost-bite, viz., cold, wet, and interference with the circulation in the leg and foot by tight puttees and boots. Lorrain-Smith, Ritchie, and Dawson[2] have investigated experimentally the pathology of the condition. The microscopic examination of the tissues showed that the chief effect of the cold is exerted on the blood-vessels, which become dilated and contain a certain amount of fibrin deposit, their internal endothelial lining becomes swollen, and the muscle fibres of the middle coat are vacuolated. The axis-cylinders of the nerves of the part become swollen and œdematous, and some slight changes in the fibres of the voluntary muscles may be observed.

Delépine (*loc. cit.*) has conducted a number of experiments on the causation and prevention of trench frost-bite. He finds that exposure to cold, dry *air* caused a lowering of temperature of the part, which, however, is slight and not progressive, but immersion in a limited amount of cold *water* caused a rapid and considerable, though not permanent, lowering of temperature, and, provided the bulk of water does not exceed twice that of the part immersed, is not detrimental. When, however, the amount of water at a temperature below that of the skin is unlimited, or if the water is limited in amount but contains ice, the lowering of temperature of the part is rapid, considerable, and progressive, and invariably results in *local frigorism,* and motion of the external water accelerates loss of heat by preventing the formation of a comparatively warm surface layer. The presence of a thick woollen covering retards loss of heat, even when saturated with water, owing to the warming of the comparatively still layer of water retained within the meshes of the fabric. It was found that a very thin layer of moderately dry air between the skin and the external cold water or ice suffices to reduce the loss of heat to an extent which is compensated by the heat brought to the part by the circulating blood. Such an air layer over the part can be secured by the use of a thin waterproof covering in combination with a woollen covering.

After many trials, Dr. Delépine has succeeded in preparing very thin and soft oil-silk, which can be made into absolutely waterproof bags for covering any part of the body by means of apposition seams. They are light, inexpensive, and wear well, should be worn over an inner woollen sock, and be protected by an outside sock. With such a combination it is possible for the men to use the boots they have at present, provided they are two sizes larger than ordinarily worn. The oil-silk bags should extend up to the knee, and could probably be made for less than 3*s.* a pair. The importance of having nothing tight round the leg is obvious—the circulation in the part should be as free as possible, so that the circulating blood may maintain the warmth of the limb.

BRITISH BIRD BOOKS.

(1) TWELVE chapters on birds by the Hon. Mrs. Murray, which have for the most part already appeared in various magazines and journals, are now reprinted, and, under the title of "A Birdlover's Year," made to synchronise with the month of the year, although in some cases the subjects dealt with have nothing in particular to do with the month under the name of which we find them.

Grasshopper warbler. From "A Birdlover's Year."

In January winter birds are discussed appropriately in some half-dozen pages. In February we as naturally consider the song thrush and its travels, chiefly in the light of Mr. W. Eagle Clarke's "Studies in Bird Migration." April suggests the return of the birds, and May the birds as builders. There are pleasant summer sketches of a "Yellow-Hammer Lane" and bird-life of the hills; and autumnal ones on October bird-life and birds as travellers. The rest deal with ocean wanderers, Tayside summer visitors, gulls and terns, and hawks and falcons. The Rev. H. N. Bonar contributes thirteen pleasing photographs of bird-life, among which we may especially notice a lapwing preparing to brood her eggs, an excellent one of a common sandpiper on her nest, and another showing that shy and elusive bird, the grasshopper warbler, going on to hers. This must have been difficult to get, and the photographer is to be congratulated. The two last are here reproduced by permission of the publishers.

Sandpiper on its nest. From "A Birdlover's Year."

(2) Mr. Thorburn's beautiful bird-studies are so well known and greatly admired that the announcement of a new work on British birds by him, to be illustrated with coloured figures, was received with considerable interest and expectation by all those of the public who concern themselves with our native avifauna. Probably it was felt by many people that if an excuse could be put forward for the issue of yet another work on the subject, that excuse might well be found in the Thorburn illustrations. The first volume of the book is now in our hands, and we can see how far our anticipations have been fulfilled. We do not think that any disappointment will be expressed (but rather the contrary), although it is probable that the original studies were even more beautiful than the plates now before us. For the latter are apparently produced by some form of the three-colour process; and it is unfortunate that in this process one of the colours sometimes obtains undue prominence, and produces shades which were not intended to appear, and doubtless

[1] (1) "A Birdlover's Year." By G. G. Murray. Pp. viii+149. (London: Eveleigh Nash, 1915.) Price 3s. 6d. net.
(2) "British Birds." Written and Illustrated by A. Thorburn. 4 vols. Vol. i., pp. 148+19 plates. (London: Longmans, Green, and Co., 1915.) Price, 4 vols., 6l. 6s. net.

did not appear in the original drawing. But these slight and unavoidable lapses are in this case so few and so little noticeable that they do not detract in any appreciable degree from the beauty and accuracy of this charming series of pictures of our birds.

A characteristic of this work is that it aims at including every species of bird which has occurred in these islands. Other earlier works have done the same. But accidental wanderers, "new to the British list," occur here from time to time so frequently that a book soon gets out of date in this respect. Indeed, these additions to the British list have poured in at such an astonishing rate of late years, especially from one district in England, that Mr. Thorburn has had the opportunity of figuring, for the first time, as British, quite a large number of birds which have, many of them unexpectedly, appeared on our list. To have not merely a figure, but a beautiful coloured figure of all these will be most acceptable, especially to those who attach any great importance to these recent additions or many of them. At all events, we are all glad to know what they look like without referring to books perhaps not very accessible. Among those birds now painted for the first time as British we may mention the dusky thrush, black and pied wheatears, thrush nightingale, subalpine and Sardinian warblers, masked shrike, and collared flycatcher; and there are a good many others also. A number of birds are figured on each plate, and this, giving as it does an opportunity of comparing at a glance two or more nearly allied species, will be a great advantage to the beginner in ornithology and to those not far advanced in the study of British birds. And it is to these, we suppose, that the book will chiefly appeal, although there will be many past-masters in the art who will not be able to resist the desire to possess such a beautiful memorial of their favourites.

Some appropriate plants, flowers, and branches, introduced and skilfully blended in the plates, are instructive as to birds' habits, and greatly add to their beauty and effect. We may mention, for instance, the gorse blossom about the Dartford warbler and the stonechat, the rosemary on which the rufous warbler is perched, and the gentian by the side of the Alpine accentor; while a yellow crocus near the cock blackbird matches his orange bill. Most of the birds were drawn from life, and are the result of many years of studies of birds from the life with this object in view. To this we owe the remarkable success the author has had in catching the characteristic attitudes of the birds depicted. When it was not possible to obtain living birds for the drawings, the author has filled up the gaps from the best preserved specimens he could procure. Of the letterpress in this work it is not necessary to say much, because, as the author points out, being more familiar with the brush than with the pen, it was his first intention that the book should be simply a sketch-book of British birds practically without letterpress. But as the work proceeded he was induced to write a short description of the various species. Thus we have a condensed account of the distribution, nest and eggs, food, song, and general habits of each species. This letterpress is admittedly and of necessity largely a compilation, but the author has inserted, in addition to what has already appeared in print, such notes as he has been able to add from his own and his friends' observations.

So far as we can see from the present volume, the author may be congratulated on having produced the most accurate series of coloured figures of British birds (as such), as well as quite the most beautiful book on the subject, which has yet appeared. The publishers are also to be congratulated on the form in which it is issued. It is beautifully printed on really good paper, and the plain red linen-cloth cover with a gold line is just what we should desire. O. V. A.

SIR ANDREW NOBLE, BT., K.C.B., F.R.S.

SIR ANDREW NOBLE, the chairman and managing director of Sir W. G. Armstrong, Whitworth and Co., died on October 22 at his residence in Argyllshire. He was a great man of business, but what was more important to his country, a great scientific artilleryman. The story of his scientific work is, in fact, the history of the development of artillery in all its branches from the time of the Crimean War to the present date.

When Noble entered the Royal Artillery in 1849, after passing through the Edinburgh Academy and the Royal Military Academy, Woolwich, line-of-battle ships were all sailing vessels; the heaviest gun weighed 95 cwt., and fired a projectile of 68 lb.; rifled guns did not exist, and little or nothing was known of the principles of internal ballistics. This state of affairs was the opportunity for a clever, energetic officer with distinct scientific ability, and Noble was not long in forcing his way to the front. After serving for a short time with Sir Edward Sabine on the magnetic survey at the Cape, he became, in 1857, secretary of the Royal Artillery Institution, and wrote his first important paper, "On the Application of the Theory of Probabilities to Artillery Practice." He had in the meantime been appointed secretary to the Committee on Rifled Cannon, and it became necessary to ascertain the relative precision of fire of the various guns which came before the Committee for report. This he accomplished by calculating for each gun the area within which it was an even chance that any one shot would strike. He introduced the phrase "probable rectangle," which has been one of the commonplaces of artillery science ever since. The method adopted was naturally that of "least squares," but in applying this celebrated theory he showed much scientific intuition. He calculated separately the probable errors in range and deflection, and thence deduced the dimensions of the rectangle.

In 1859 Noble became secretary of the Com-

mittee on Plates and Guns, received the appointment of Assistant Inspector of Artillery, and entered the proof department of Woolwich Arsenal. Almost immediately after this he was made an associate member of the Ordnance Select Committee and a member of the Committee on Explosives. He was thus in closest touch with the burning questions that presented themselves for solution on the introduction of rifled guns. At this time (1860) the Government might possibly have secured his services for a further considerable period if they had promptly offered him a position suited to his growing reputation as a gunner of original ideas and untiring energy; but the Government acted too late, and a good offer found that he had already bound himself by contract to enter the Elswick firm as the director of its ordnance department. He, however, was retained on several Government committees, upon which his presence was invaluable, as he had the means at Elswick of carrying out many special researches, the results of which he freely placed at the disposal of the Government.

Noble's first important work in exterior ballistics appears to have been his experiments with the electro-ballistic apparatus of Navez, which had the object of making a close determination of initial velocity. He ascertained the causes which affect the velocity both with smooth-bore and rifled guns, and in particular he showed that with reduced powder charges the air-space in the powder chamber had a notable effect. He also discussed at length the law of dependence of the resistance of the air upon velocity in connection with previous researches of Probert, St. Robert, Mayevski, and Didion. The next paper, "On the Ratio between the Forces tending to produce Translation and Rotation in the Bores of Rifled Guns," was of much importance at the time it was written. Rifled guns were getting bigger every day, and there was much difference of opinion as to the best method of rifling and, in particular, as to the relative merits of uniform and increasing twist. He showed that with the uniform twist the force required to give rotation was only a small fraction of that required to give translation, and that in all cases the increment of gaseous pressure due to rifling was insignificant. With regard to the increasing twist (parabolic system of rifling) he also made a thorough mathematical investigation, and found again that the pressure on the studs due to rifling is only about 2¼ per cent. of the pressure required to give translation; also that the substitution of parabolic for uniform rifling reduces by about one-half the maximum pressure on the studs; and that the increment of gaseous pressure due to rifling, tending to burst the gun, is exceedingly small and less than that which obtains when the rifling is uniform.

His researches in interior ballistics properly so called commenced when he first went to Elswick, but the first publication appears to have been in the Proc. Roy. Inst. for 1871, "On the Tension of Fired Gunpowder." Previous investigators, de la Hire, Robins, Count Rumford, Cavalli, Neumann, Mayevski, Rodman, had obtained results for the pressure exerted by gunpowder fired in a closed vessel varying from 1000 to 100,000 atmospheres. Bunsen and Schischkoff later found 4374 atmospheres, about 29 tons on the square inch, for the pressure which the gases may approximate to but can never reach. Commencing in the year 1861, Noble, in conjunction with Sir W. Armstrong, carried out a large number of experiments, employing a chronoscope specially invented by himself. This beautiful instrument was able to measure a millionth of a second of time with ease. It was used in conjunction with a series of crusher gauges in determining the pressures exerted by the powder gases at various places along the bore extending from the powder chamber to the muzzle. The results were of first-rate importance. It was shown that the maximum pressure of fired ordinary gunpowder of unit density is not much above 40 tons to the square inch, but that in large guns, owing to the violent oscillations produced by the ignition of a large mass of powder, the pressure is liable to be locally exalted to an extent which endangers the endurance of the gun while detracting from the useful effect. It was also found that the intensity of this wave action is directly influenced by the position of the vent or firing point, and that it is desirable to have as short a powder cartridge as possible.

Noble's remaining researches in gunnery, extending over nearly fifty years, may be for the most part summed up under the title "Researches on Explosives." In these he was for many years associated with Sir Frederick Abel and Sir James Dewar. The objects in view were to ascertain the products of combustion of powders fired in circumstances similar to those which exist in guns—to ascertain the pressure exerted by the products of combustion at the moment of explosion and the law of its variation with the gravimetric density; to find the influence of the size of grain; to find the effect upon the products of a change in the pressure under which firing takes place; to measure the volume of the permanent gases liberated; to compare the explosion in a closed chamber with that in the powder chamber of a gun; to find the heat generated; and, finally, the work which the explosive is capable of performing on a projectile in the bore of a gun. That this lengthy programme was successfully carried out was largely due to Noble's extraordinary ability and energy. The results obtained were of the utmost importance to the manufacture of guns of all calibres. When fired in a closed space the temperature of the explosion of gunpowder was found to be 2200° C. The total work of gunpowder when indefinitely expanded was found to be 332,000 grm.-metres per gramme of powder, or 486 foot-tons per lb. of powder.

It is impossible in this short notice to say more upon these results, which are fully set forth in communications printed in the Transactions of the Royal Society between the years 1875 and 1879. The experiments were repeated as gunpowder gradually altered in physical characters,

and ultimately, when the cordite explosives were under consideration, a new set of experiments pointed out the modifications in gun construction that were necessary. It may safely be said that Noble threw light upon every question of internal ballistics. No doubt at Elswick he had very great facilities, but these would have been of no avail if he had not supplied practical knowledge and scientific insight, and supported these by his vigorous mind and untiring energy. It has been said that when a problem has been correctly stated, much has been already done towards its solution. When internal ballistics was in a state of chaos, Noble was able to extract the real questions from much that was irrelevant, and to give them a scientific statement. The result of his work has been that the splendid guns which we possess in the Navy and Army are at least as good as any in the world. It is certain that no history of gunnery will be complete which does not devote much space to a description of his pioneer work. That work was recognised on two occasions by the Royal Society: in 1870, when he was elected to the Fellowship, and in 1880, when he was awarded a Royal Medal.

P. A. M.

DR. R. ASSHETON, F.R.S.

BRITISH zoology, which recently sustained a severe loss by the death of Prof. Minchin, has received a second blow by the unexpected death of Dr. R. Assheton, which occurred at his residence, Riverside, Grantchester, near Cambridge, on October 24.

Dr. Assheton was born at Downham Hall in Lancashire in 1863, and belonged to an old Lancashire family. He was educated at Eton and afterwards entered Trinity College, Cambridge, where he came under the influence of the new school of embryology founded by Foster and Balfour and ably carried on by Sedgwick. He read for the Natural Sciences Tripos, in which he took first-class honours when he graduated in 1886. Thereafter he devoted himself to research in embryology, and was not long in making a name for himself. In 1889 he was appointed lecturer in zoology under Prof. Milnes Marshall in Victoria University, Manchester, and he held this post until Prof. Marshall's death in 1893. In 1901 he was appointed lecturer in biology to the medical school in Guy's Hospital, and took up his residence in Grantchester; he resigned this office in 1914 in order to give his whole time to teaching and research in Cambridge, where he was appointed lecturer in animal embryology. In the same year he received the well-merited honour of election into the Royal Society.

Assheton's earlier work was concerned with the difficult subject of mammalian embryology, and especially with the earlier stages of development and the beginnings of the placenta. He undertook a costly series of investigations into the early development of the sheep, and arrived at a novel view of the origin of the wall of the blastoderm vesicle from which the fœtal part of the placenta is principally derived. This he considered to be endodermic, not, as had always previously been believed, ectodermic. We think that this view is not adequately supported by the evidence which he adduced, and that it will scarcely survive. But Assheton did not by any means confine himself to mammalian embryology. The early stages of development of the frog, and the development of the curious Egyptian fish, *Gymnarchus niloticus*, also became the subjects of his researches.

From the very beginning of his work there was one feature by which Assheton was distinguished from most of his contemporaries. He was not content either with the simple description of developmental processes or with the search for their phylogenetic significance. In every case he endeavoured to analyse these processes into the differential rates of growth which underlay them, and then to find reasons for the differential rates of growth in differences of nutrition. He was, in a word, the first experimental embryologist in England. He succeeded in opening the hen's egg and keeping it still alive and developing for some days, and in this way he was able to watch the development of one and the same embryo, and by suitable tests to measure its growth. At a time when many embryologists were inclined to accept the view of His, that the nervous and skeletal axes of vertebrates were built up by the gradual concrescence of two lips bordering an elongated slit, Assheton was able to show that this view was an entire misinterpretation of the events, and to propound a solution which substituted for the alleged concrescence a growth in length of the embryo which he called *deuterogenesis*. All subsequent careful work has supported Assheton's view. Finally, in a paper entitled "The Geometrical Relation of the Nuclei in an Invaginating Gastrula (Amphioxus), considered in connection with cell-rhythm and Driesch's conception of entelechy," he measured swords with the "entelechy" of Driesch, and in substituting for that mystical factor a simple force which may well be of chemical or physical nature. At the time of his death Dr. Assheton was engaged in the preparation of a text-book of the embryology of mammalia. If this work was at all near completion it is to be hoped that it may be published, as otherwise a most valuable compilation of facts and a storehouse of illuminating ideas would be lost to science.

Dr. Assheton married a daughter of Sir Thomas Bazley, Bart., and is survived by his widow, one son, and two daughters. His son is serving as an officer in the 1st Cambridgeshire Regiment. He had a most charming personality which attracted all who knew him, and his loss will be deeply regretted by a wide circle of colleagues and friends.

E. W. M.

NOTES.

WE notice with deep regret the announcement of the death, on November 1, at sixty-seven years of age, of Sir Arthur Rücker, F.R.S., principal of the University of London from 1901 to 1908, and previously professor of physics at the Royal College of Science, South Kensington.

THE death is announced, on October 30, in his eighty-fourth year, of Lord Welby, president of the Royal Statistical Society, and for many years permanent secretary to the Treasury.

THE ninetieth illustrated Christmas course of juvenile lectures, founded at the Royal Institution in 1826 by Michael Faraday, will be delivered this year by Prof. H. H. Turner, his title being "Wireless Messages from the Stars."

THE director of the Meteorological Office reports that information has been received from the Seismological Observatory at Eskdalemuir, Scotland, of the record of a large earthquake which occurred at 7 a.m. on November 1, in or near Japan.

WE learn from the *Times* that the Nobel Prize for Medicine for 1914, of the value of about 8000*l*., has been awarded to Dr. Robert Bārany, professor of otology in the University of Vienna, for his work on the physiology and pathology of the vestibule of the ear. The prize for medicine for 1915 is reserved until next year.

PROF. KAMERLINGH ONNES announces in the *Nieuwe Rotterdamsche Courant* that he has received news from Vienna of the death of Prof. F. Hasenöhrl, professor of physics in the University of Vienna, who was killed in action on the Italian front. The deceased, who was a pupil of Boltzmann, began in 1899 an investigation on the dielectric constants of liquefied gases, in the cryogenic laboratory at Leyden. Having returned to Vienna, he became privat-dozent, and later succeeded Boltzmann, whose collected papers he edited with much care. Earlier in the war in Galicia, Prof. Hasenöhrl had been wounded in the shoulder, but after a complete recovery he again went to the front, where his lamented death occurred.

THE Naval Consultation Board appointed by national scientific and engineering societies at the request of the secretary of the U.S. Navy, has approved a plan for the establishment of a research and experimental laboratory for the Navy. It is recommended that the laboratory should be situated on tide water of sufficient depth to permit a "Dreadnought" to come to the dock. It should also be of complete equipment, to enable working models to be made and tested to destruction. The Board suggests that the investment for grounds, buildings, and equipment should total approximately 1,000,000*l*.; and the annual working expenses should be between 500,000*l*. and 600,000*l*.

A NOTE in *Engineering* for October 29 gives some particulars of the new monitors. Without accepting as technically accurate the somewhat picturesque details published in official accounts, it may be assumed that the Admiralty designers have succeeded in producing vessels with the heaviest of guns which are practically immune from torpedo attack. Some mount 14-in. guns in a central turret, others have one 9·2 in. bow and one 6-in. stern guns, and others, again, two 6-in. guns. The 14-in. guns fire projectiles of ¾ ton weight, and the range is 15 miles. Our 6-in. gun "throws 100 lb. of high explosive 12 miles without overreaching itself." The vessels are not of great speed—this is not required. Only six months elapsed from the time that the demand for their design was made until they fired their first shot. It is a great credit to all concerned, notably to the workmen in the shipyards, that this need was so promptly met.

THE *Morning Post* of November 2 publishes the following message from its Paris correspondent referring to the close relations now possible between science and the French Army:—By becoming Minister of Public Instruction and Inventions Affecting National Defence in the new French Cabinet, M. Painlevé will, it is hoped, be able to place the inventive skill of the nation more directly at the disposal of the Ministry of War. He has served for a considerable period as President of the Inventions Committee, and during his tenure of that office it became evident to him that every effort ought to be made to organise scientific skill and to co-ordinate effort. In his new capacity he becomes the sole intermediary between the world of science and the Army. Under the system now established one of the ways in which the Ministry will be useful to the country is that it enables the Army whenever the need arises to appeal directly to men of science for the solution of any scientific problem.

THE name of Dr. Philippe Hatt, whose death, at the age of seventy-five, we regret to announce, will be more familiar to the astronomers of the last generation than to those of the present. In the middle of the last century, when Government expeditions for scientific purposes were frequent, M. Hatt rendered good service. He organised and took part in the French Expedition to Wha Tonne, in the Malay Peninsula, where the eclipse of 1868 was successfully observed by Rayet, Tisserand, and others. 1874 found him on the bleak, inhospitable rock known as Campbell Island, to observe the transit of Venus. With André he went to the Rocky Mountains for the observation of the solar eclipse of 1878, and four years later he had a prominent place in the French Expedition to Chubut to observe the second transit of Venus. Less sensational, but equally meritorious, work M. Hatt achieved in the course of his professional career as a hydrographic engineer. So far back as 1866 he was entrusted with the task of making a new survey of the coast of Cambodia, and the lower course of the River Saigon. At the time of the French annexation of the country he explored the Gulf of Siam, and demonstrated the value of Gahn-Ray Bay as the site of a commercial port. Later he devoted himself to hydrographic work on the French coast, to the triangulation of Corsica, and the observation of tidal phenomena, concerning which he produced some valuable memoirs. He was elected in 1897 a member of the French Academy of Sciences, in the section of geography and navigation, in succession to M. Antoine d'Abbadie.

It is claimed that a Swedish engineer, M. Wulff Normelli, has invented an ammonium nitrate explosive, Normellite, which has a bursting effect 25 per cent. better than that of any other explosive. It is claimed also to be safer than most explosives, being very insensitive to shock. This latter is characteristic of ammonium nitrate explosives, which require a powerful detonator, and frequently a priming of the loose explosive. Since Favier took out his patents in 1884-85 for an ammonium nitrate powder containing naphthalene, paraffin, and resin, very many explosives of this class have been introduced. The hygroscopic nature of the salt necessitates enclosing the explosive in some waterproof envelope. On account of the low temperature on firing and the production of little or no flame-producing gases, this class of explosives is particularly favoured for use in fiery coal mines. With the nitrate all kinds of combustible materials are employed, such as di- and tri-nitrotoluene, dinitronaphthalene, charcoal, etc. Other nitrates are frequently substituted for a portion of the ammonium nitrate. Roth in 1900 took out patents for the use of aluminium powder in such explosives, the idea being to utilise the high temperature attained by the oxidation of this metal, and thus greatly increase the power. Ammonal is such a mixture, containing, in addition to the nitrate and aluminium, trinitrotoluene and charcoal. It has been claimed that ammonal is a very powerful explosive, and is more effective than a similar weight of cast picric acid (lyddite) in breaking up a shell. It is therefore not improbable that Normellite is an explosive of similar type to ammonal.

The council of the Chemical Society has sent to every fellow a letter directing attention to the Government scheme for the organisation and development of scientific and industrial research. In accordance with this scheme, a Committee of the Privy Council has been appointed, and also an Advisory Council of scientific men whose primary functions are to advise the Committee of Council on—(i) proposals for instituting specific researches; (ii) proposals for establishing or developing special institutions or departments of existing institutions for the scientific study of problems affecting particular industries and trades; (iii) the establishment and award of research studentships and fellowships. The council of the Chemical Society considers it to be the urgent duty of every fellow to render all assistance possible to the Advisory Council by suggesting suitable subjects for research. As pointed out in the White Paper, the results of all researches financed by public funds will be made available under proper conditions for the public advantage, and the council feels assured that every fellow will place patriotic duty before private gain at such a time. Suggestions for purely scientific researches will be appreciated, but those having a direct bearing on chemical industry and its promotion will naturally receive a preference. Suggestions should be sent to the council of the Chemical Society, Burlington House, W.; those suggestions which are considered suitable to receive the financial aid indicated by the scheme will be forwarded to the Advisory Council.

The committee which was constituted last year to promote testimonials to Profs. Perry and Harrison on their retirement from the staff of the Imperial College (Royal College of Science) has now completed its labours. We are informed that in each case there was a gratifying response to the appeal to former students and colleagues for subscriptions, and that the committee has thereby been enabled to carry out its purposes completely. The testimonial to Prof. Harrison, who had been associated with the department of mathematics and mechanics during thirty-two years, has taken the form of an illuminated address, accompanied by valuable personal gifts. In the case of Prof. Perry, former students of the Finsbury Technical College desired to be associated with the testimonial, in recognition of his valuable services to that institution prior to his joining the staff of the Royal College of Science in 1896. The governing body of the Imperial College having readily consented to act as trustees, the aim of the committee was to establish a permanent memorial of Prof. Perry's work in the form of a medal or prize to be awarded annually at each of the two institutions. In view of Prof. Perry's desire that the testimonial should not include a personal gift, the whole of the subscriptions became available for the founding and endowment of medals. Dies have been prepared from designs by Mr. Charles Wheeler, of the Royal College of Art, and these, together with a stock of medals, and a certificate for 4½ per cent. War Loan Stock, have recently been placed in the custody of the Imperial College. A silver medal will be awarded annually to a student of the Imperial College for distinction in mathematics and mechanics, and at the Finsbury College a similar award will be made for distinction in mathematics and engineering. The governing body has expressed its high appreciation of the committee's decision in associating the Perry medal, and the administration of the fund, with the Imperial College, and has stated that the gift is regarded as a fitting testimony to the inspiring personality of one who took such a prominent part, both in the Royal College of Science and in the Imperial College, in the teaching of mathematics and mechanics. Prof. Perry has also expressed his gratitude for the honour which has been conferred upon him by the subscribers, and by the Imperial College. The obverse of the medal is a striking portrait, and a plaster copy of the original large model has been presented to Prof. Perry.

The report of the Government Museum at Madras for 1914-15 is a record of steady progress. The pre historic collections of Mr. R. Bruce Foote have been rearranged, and the Hindu, Buddhist, and Jain sculptures, which include an important collection from the Amaravati Stupa, have been classified. Considerable stores of Roman coins which are being discovered year by year, including those of the Emperors Nero, Trajan, and the Empress Faustina, illustrate the important trade intercourse between Rome and southern India in the early period after the Christian era.

The Museum Journal of the University of Philadelphia for March, 1915, but only recently received, is

almost entirely devoted to an account of the expedition under Dr. Farabee, which has now been nearly two years in the field. His first journey had for its object the exploration of the boundaries of Venezuela and Brazil. He then visited the Macusi tribe in southern British Guiana, a most perilous undertaking. He next started for the upper waters of the Amazon and conducted archæological investigations on the island of Marajo, near the mouth of the river. From there he again proceeded to the Upper Amazon. Large ethnological collections have been made, but these cannot be fully examined until the expedition returns to the United States. Meanwhile this preliminary report, illustrated by a fine collection of photographs, is of much interest.

HIS HONOUR JUDGE J. S. UDAL contributes to the September issue of *Folk-lore* an interesting account of the practices connected with what is known as the Obeah cult in the West Indies. These include the worship of the criboe, a large black, non-venomous serpent, and some ghastly rites of human sacrifice. It has been asserted by some writers that these practices have now ceased, but Mr. Udal has collected a large mass of evidence from law proceedings and other authoritative sources to prove that this is not the case. He ends by expressing the hope that "now that the consciences of the public of our West Indian colonies and of the Home Government have begun to realise to what terrible lengths any indulgence towards or weakening in the repressive enactments against this widespread plague of Obeah may lead, that we shall see the rapid disappearance of any objectionable features in its cult, leaving only, it may be, a harmless residuum that may still afford some interest to the student and lover of folk-lore."

THE *Psychological Review* (vol. xxii., No. 4) contains an interesting summary of an "Experimental Investigation of the Subconscious," by Miss L. J. Martin. In view of the great interest now being shown in the treatment of mental diseases by psychological means, any method which enables the physician to penetrate below the threshold of consciousness is at least worthy of consideration. The Freudian technique of psycho-analysis requires a long training, and even so, is open to various objections. Hypnotic methods are not always possible or suitable. Miss Martin claims that the "image" method has certain definite advantages over the methods usually adopted for tapping the subconscious.

AN article on "Variability in Performance during Brief Periods of Work," which appears in the *Psychological Review* (vol. xxii., No. 5), has some bearing on a problem of great moment at the present time. Investigations into the conditions of, and remedies for, industrial fatigue are now occupying the attention of a committee of the British Association, and any contribution to the processes involved in work of any nature may be significant. This paper shows that an individual varies in the success of his performance of given tasks even though these last but one minute. The authors, as a result of their experiments, think it probable that mental fatigue is not as rare as is sometimes supposed, but that the repair process is so rapid, compared with muscle repair, that, as work is usually done, the loss may be compensated for during brief intervals of relaxation.

THOSE responsible for the care of museums will welcome the "General Guide to the Collections in the Manchester Museum," which has just been published by Messrs. Longmans, Green and Co. at the modest price of 3*d*. It is a model of what such guides should be, and is admirably illustrated. Perhaps its most interesting section is that on Egyptology, which contains a tabular statement of the various periods of Egyptian history from the pre-dynastic to the Roman, with the dates of each according to Petrie and Breasted.

DR. J. M. DEWAR, in the *Zoologist* for October, continues his notes on "The Relation of the Oyster-catcher to its Natural Environment," discussing, in this section, the summer environment. Though, during most of the year, a dweller by the seashore, this species shows a marked preference for an inland breeding-place. The area chosen by Dr. Dewar for his observation station is typical of its kind, and his notes should be carefully read in comparison with the accounts which have been given of the reproductive period of individuals which, perhaps for lack of suitable inland stations, establish their nurseries by the seashore. This number also contains same interesting notes by Mr. G. T. Rope on the vagaries of choice displayed by cats in the matter of diet, citing numerous instances where earthworms, fungi, raw potatoes, baked pears, tomatoes, cucumbers, and marrow-seeds were preferred to a meat diet.

A VALUABLE summary on the "Status, Plumages, and Habits of the Wren of St. Kilda," by Mr. W. Eagle Clarke, appears in the *Scottish Naturalist* for October. The St. Kilda wren is one of the most interesting of the five-and-twenty endemic species now recognised by the British Ornithologists' Union, and though made known more than thirty years ago, this is the best account yet given of its habits, plumages, and relation to environment. In the same issue Mr. William Taylor records the "History of the Triassic Reptile *Scleromochlus taylori*." Dr. A. Smith Woodward, it may be remembered, some years ago expressed the opinion that this very fragmentary fossil should be regarded as a diminutive bipedal dinosaur, with a jerboa-like mode of locomotion. Baron von Huene now comes to the conclusion that it was not a crawling, walking, or jumping animal, but that its short, spreading hands and long feet show it to be well suited for climbing trees, and that it may have possessed some kind of flying membrane, recalling the bat in this respect. On the whole, we incline to think Dr. Smith Woodward's view is much the more probable.

IN Bulletin No. 20 of the Department of Agriculture, Ceylon, on "The Effect of Different Intervals between Successive Tappings of *Hevea brasiliensis*." the interesting conclusion is reached that after five years' continuous tapping there is no evidence that the yield obtained in a given time by tapping at an interval of five or seven days will ultimately exceed that obtained by more frequent tapping.

THE recently issued part (part i., vol. vi.) of the Annals of the Royal Botanic Gardens, Peradeniya, is almost entirely occupied by a series of papers by Mr. T. Petch, the Government botanist. Of these the most important contribution is that on "Horse-hair Blights," belonging to the genus Marasmius. *M. equicrinis* is the common species of the eastern tropics, while *M. sarmentosus* is the species found in the West Indies. Mr. Petch devotes his attention to the Ceylon species, which are described in some detail and illustrated by an excellent series of plates. The mycelium of these fungi is thin and rhizomorphic, and spreads freely over bushes and trees at some height above the ground; the pileus is borne on a slender petiole, and bears only a small number of gills.

A COLLECTION of fungi from Australia and New Zealand made by Mr. W. N. Cheeseman during the visit of the British Association to Australia and New Zealand last year is described by Miss E. M. Wakefield in Kew Bulletin No. 8. Twenty-eight of the 100 species enumerated are endemic to Australia, and these include the seven new species described. Five of the new species show close affinity with European or North American types. Forty-eight species were found to be common to Europe or North America, sixteen to the tropics of Africa and the East, and six cosmopolitan in the tropics generally. Only two species occur in the tropics of South America as well as in Australia. Attention was paid especially to the Polyporaceæ and Thelephoraceæ, and the collection consists mainly of specimens belonging to these groups. The principal features of the new species are illustrated in the plates.

Symons's Meteorological Magazine for October gives some very interesting details on the rains for September, which varied considerably in different parts of the British Isles. The rainfall table shows an excess of rain in parts of Scotland and in the south-east of England, whilst elsewhere there was a deficiency. At Gordon Castle the excess for the month amounts to 3·17 in., the fall being 222 per cent. of the average, whilst at Seathwaite the deficiency for the month was 9·20 in., the fall being only 18 per cent. of the average. A special article is given on the floods in the north-east of Scotland which occurred in the closing week of September, when the floods are stated not to have been equalled in many districts since the famous Moray floods of August, 1829. The area of maximum rainfall was located on the shores of Moray Firth, near Inverness, the fall for the twenty-four hours on September 25 being 4·07 in. at Fortrose, 3·78 in. at Nairn, and 3·64 in. at Inverness. The total fall for the three rain days September 24, 25, and 26 amounted to 5·47 in. at Nairn, the rain really falling in about forty hours. The river at Nairn overflowed its banks and occasioned much damage, whilst sixteen bridges and culverts were carried away. The Daily Weather Charts issued by the Meteorological Office show very distinctly the advance and movement of the cyclonic disturbance which occasioned the rainfall, the central area being situated over the south of Scotland on the morning of September 25. The rainfall in the south-east of England on September 29, which caused an excess for the month, was due to the passage of a cyclonic disturbance along the English Channel, and centred over the Straits of Dover on September 29.

AN interesting account of attempts to improve the somewhat primitive methods used in certain of the native industries of India is found in a paper by Mr. A. Chatterton, in Bulletin No. 55 of the Agricultural Research Institute, Pusa. It deals with the manufacture of jaggery in South India, and gives an account of experiments made to introduce power-driven sugar-cane mills as a substitute for the bullock-driven mills hitherto universally used. A description is also given of improvements in methods of evaporation introduced with the object of increasing the yields obtained from the juice; with the existing wasteful methods these are far lower than they should be.

THE October number of the Journal of the Röntgen Society contains the interim report of the committee on the standardisation of X-rays when administered for medical purposes. It mentions most of the methods of determining the quality or hardness and the intensity of the X-rays falling on a surface, with the intention of providing a proper basis for a more extended discussion of the relative merits of the various methods at a later date. On the whole the report seems in favour of the half-value method of determining quality. The rays are sent through a stepped wedge of a standard material—generally bakelite—and fall on a fluorescent screen. Beside the wedge is placed a metal plate with holes through it which remove half its material, and the step of the wedge which gives, on the screen, the same intensity of image as the metal plate is noted. For determinations of intensity the report apparently approves some form of ionisation method, as most of the other methods give undue weight to the softer rays.

AN important paper on the theory of grinding was read at the Institution of Mechanical Engineers on October 15 by Mr. J. J. Guest, of Birmingham. Apart from side issues, the speed limit of the grinding wheel is controlled by the strength of the material of the wheel, and for reasons of production the wheel is to be used at the highest safe surface-velocity. The author considers that the component of the work-velocity which is normal to the wheel surface (termed the "normal material velocity") is the fundamental controlling factor. This velocity is given by

$$v_1 = v\sqrt{2t\frac{d+D}{dD}},$$

where v is the surface velocity of the work, t is the reduction in diameter being effected, and D and d are the diameters of the wheel and work respectively. This quantity, as has been said, is the controlling factor, and if it is too large the wheel will wear unduly, while if it is too small the wheel will glaze. Again, the work done in grinding off metal is proportional to the volume removed, *i.e.* the rate of grinding, $\frac{1}{2}vtc$, depends on the power used, c being the traverse. vtc cannot exceed a certain amount, b, and for production reasons should be kept up to that amount, hence $vt = b/c$, together with the above

equation, will serve to determine the values of v and t for any particular case, and are sufficient for the purpose. The author gives several numerical applications of this theory, which appears to be of general application in the selection of speeds in plain and internal work.

THE *Engineering Magazine* for October contains an article on the forests of the United States, by Mr. Leonard Lundgren. Before the coming of the white man these forests covered an area of about 800 million acres, and contained about 5200 billion board feet of lumber. Fire has destroyed as much timber as has been utilised for industrial purposes, and as much again has been wasted through poor logging and milling operations, and through clearing land for agricultural purposes. The forests at present cover an area of 550 million acres, and contain about 2900 billion board feet of lumber. Seventy-six per cent. of this is owned privately, 21 per cent. is held by the United States in the national forests, and 3 per cent. is on other public lands. The annual cut is approximately 43 billion board feet; at this rate, if there were no new growth and the present demand were maintained, the timber supply would last about sixty-five years. It is reasonable to expect that all agricultural lands, cultivated or uncultivated, will ultimately be placed under crops that will give the greatest economic return. Some of the lands now under cultivation will unquestionably revert to forest. Through reducing the per capita consumption (at present amounting to 260 cubic feet of wood per inhabitant), protection against fire, and increasing the natural growth per acre by the practice of forestry, it is probable that a balance between production and consumption will eventually be reached by the force of natural economic laws. In Saxony, where forestry has been practised for many years, the annual production is 93 cubic feet per acre. Forestry is practised in the United States on Government and State lands only, and the estimated annual production is 12 cubic feet per acre.

MESSRS. CONSTABLE AND CO., LTD., 10 Orange Street, London, W.C., inform us that they now publish in this country, at 6s. 6d. net, Prof. L. T. More's "The Limitations of Science," reviewed in the issue of NATURE of September 2 last (vol. xcvi., p. 3).

OUR ASTRONOMICAL COLUMN.

THE ANDROMEDA NEBULA.—According to a notice in the September Journal of the Royal Astronomical Society of Canada, a determination made at Mount Wilson of the radial velocity of this nebula indicates a recessional motion of 329 km./sec. from measures of nine lines. The spectrogram was obtained on five consecutive nights during last November (thirty-four hours' exposure), by means of a small slit spectrograph at the primary focus of the 60-in. reflector. There is stated to be no evidence of either bright lines or rotational displacement.

A LONG-PERIOD SPECTROSCOPIC BINARY.—Mr. J. B. Cannon has made a determination of the orbital elements of μ Persei, a spectroscopic binary having the somewhat long period of 284 days. The spectrum is of the solar type, and a number of lines being available for measures, a good determination of velocity could be made. Forty-eight plates secured during 1913–15 were measured, and combined to give 0·11 normal places, the velocity-curve coming out very nearly symmetrical. A range of velocity of 41 km. is indicated, whilst 39 km. was found from seven Lick spectra.

SUN-SPOTS AND TEMPERATURES.—In continuation of the statistical investigation of the question of seasonal variations of weather Dr. Gilbert T. Walker publishes (Memoirs of the Indian Meteorological Department, vol. xxi., part xi., p. 61) a paper giving the correlation coefficients of sun-spots with temperature for a large number of stations generally distributed over the earth's surface. A paradoxical defect of temperature associated with times of maximum sun-spots is revealed for a large number of stations, more especially tropical. An area of positive coefficients, however, stretches from the Arctic over the western parts of Europe.

THE UNION OBSERVATORY.—Circulars Nos. 26 and 27 have recently come to hand. The first of these gives details in continuation of the investigation by blink-microscope of the variable stars in the region of η Argus. A table is given showing the results of special search for known variables not picked up in the first survey. The variability of a star (R.A. 10h. 9m. 36s., declination $-58°$ 24·3′ (1875), announced last year by Dr. A. W. Roberts, is confirmed.

In the other circular Mr. J. Voûte gives the results of measures of sixty-seven double stars, employing the Bosler-Salet inverting prism to eliminate systematic errors in the measurement of position angles. The instrument used was the 9-in. Grubb refractor. It was specially desired to obtain experience of the working of the method under additional instrumental conditions in extension of measures made at Leyden and at the Cape. In this process the position-angle is determined as the mean of measures made before and after inverting the field by means of a prism. The present results are in good agreement with the Leyden series, amply supporting the favourable opinions regarding the method.

A message from the observatory, dated October 7, informs us that a 12th magnitude star, with a proper motion of 5·1″ a year, has been found with the blink apparatus. Full particulars will be given in a forthcoming Union Observatory Circular. The place of the star is (1900) R.A. 14h. 22·9m., declination $-62°$ 2′.

THE ORBIT OF B.A.C. 5890.—A noteworthy spectroscopic investigation of this binary system has been made by Mr. F. H. Parker at the Dominion Observatory, Ottawa (*Jour. Roy. Astr. Soc.*, Canada, September). The reductions are based entirely on pairs of measures made on plates showing spectra of both components. Nineteen such plates were secured at Ottawa, but the dispersion only sufficed to separate the lines near primary maximum. However, one of three Lick spectra showing double lines was taken near apastron, thus fortunately bridging the gap. The measures of the Canadian plates were grouped into five normal places, those from the Lick plates giving three additional points. The photographic magnitude of the star is 4·9, the spectrum being of the F type, and the lines are described as "broad." The masses of the components are very nearly equal (25 : 24). The period is 26·27 days, whilst the eccentricity has the rather large value 0·49. This is not altogether exceptional, for, curiously enough, binaries having periods 12–30 days yield an average value of 0·462, according to the data recently collected by Dr. Sven Wicksell.

IRON AND ALLOTROPY.

MANY points of theoretical interest as well as of practical importance were brought forward in the discussion "On the Transformation of Pure Iron" opened by Dr. A. E. Oxley, of the University of Sheffield, at the Faraday Society on October 19. The subjoined summary describes the main views presented.

It is now believed by many metallurgists that the A_2 transformation of iron can be explained without assuming allotropic change, but the A_3 transformation is regarded as involving allotropy. The crystalline state is one of extreme molecular association (physical polymerism or the grouping of chemical molecules under the influence of mutual physical forces), and if allotropy is determined solely by the nature and extent of this association each substance will show an unlimited number of allotropic forms within a finite temperature interval. On this view the attempts to show that A_3 involves allotropic change while A_2 does not, need not have been made.

To surmount the difficulty presented by the existence of so many allotropes, two different types of allotropy have been recognised: (1) the two-phase (discontinuous) type, (2) the one-phase (continuous) type. Having adopted these, we have now to determine experimentally to which type a given transformation belongs. The burden is thus thrown on our experimental refinements, and the difficulty of drawing a sharp distinction is at once apparent—the distinction can only be arbitrary. In this connection the liquid crystalline state is interesting. There are some substances which show no liquid crystalline state on fusion, but do so prior to recrystallisation. Thus we have two-phase allotropy on heating and one-phase allotropy on cooling.

Defining allotropy as a difference of atomic structure of the chemical molecule (consistent with the transformation from oxygen to ozone, or from one isomer to another), a distinction can be drawn between allotropy and crystalline grouping. Allotropic modifications will form characteristic space lattices determined by their molecular constitutions. It does not necessarily follow that a difference of crystalline symmetry implies allotropy, for *identical* molecules can be packed together in different ways (Barlow and Pope, Trans. Chem. Soc., vol. lxxxix., p. 1741, 1906). We must distinguish between the forces holding the molecules in a definite space lattice and those holding the atoms in the molecule.

Now on the theory of the molecular field Weiss has shown (*Comptes rendus*, vol. cxliv., p. 25, 1907) that the so-called β and γ forms of iron have the same Curie constant, and A_3 is not an allotropic change point. In a later research (*Journ. de Phys.*, vol. I., p. 965, 1911, and *Arch. des Sciences*, 1913), using more recent data, ***and assuming that each atom possesses an integral number of magnetons***, Weiss shows that the transition β to γ may be represented by a change from a tri-atomic to a di-atomic molecule. If, however, the magnetic particle of the γ state consists of three molecules, and that of the β state of two molecules, the magneton theory will still hold, but now the number of atoms in a molecule of each state is the same. This latter view seems more probable, for γ iron possesses more magnetons per molecule than β iron does, and therefore unless we suppose that the molecules of the β state are so bound together that one cannot rotate without dragging along its neighbours, it seems difficult to account for the rapid increase of susceptibility on cooling through A_2.

If cooling through A_2 is accompanied by a closer grouping of the molecules in the direction (characteristic for each crystal) of spontaneous magnetisation, there will be no change of crystalline symmetry, while the increased interaction of the molecules will give rise to ferro-magnetism. The change of molecular distances in the perpendicular directions is not important from a magnetic point of view, each molecule being mainly constrained by the one in front and the one behind in the direction of the magnetic axis. (Silver iodide (hexagonal) is an example of a crystal which expands along the axis while contracting in perpendicular directions.) Thus this interpretation is not necessarily inconsistent with known magneto-striction data or with determinations of thermal expansion (linear or volume) of a *mass* of iron crystals.

The thermal evolution at A_2 is due to the readjustment of molecular distances. The rise of temperature observed is 14° C. (Arnold, B.A. Report, Sheffield, 1910), and taking 0·1 as the specific heat of iron, the thermal evolution is 1·4 cals./gram. This value is small compared with the latent heat of fusion of elements, *e.g.* P (5), Bi (13), Cd (14), Pb (5), Ag (22), Sn (14), Zn (28), Ga (19). Further these latent heats are in general small compared with the thermal evolutions in known allotropic and isomeric transformations. Thus

Allotropic	96 gr. ozone = 96 gr. oxygen + 59,200 gr. cals. 31 gr. yellow phosphorus = 31 gr. red phosphorus + 21,000 gr. cals.
Isomeric	78 gr. dipropargyl = 78 gr. benzene + 100,000 gr. cals. 58 gr. allyl alcohol = 58 gr. acetone + 18,600 gr. cals. = 58 gr. propaldehyde + 22,600 gr. cals.[1]

The transition $2O_3 \longrightarrow 3O_2$ has the thermal value +600 cals./grm. The transition $\beta \longrightarrow \gamma$ in iron has the thermal value −1·4 cals./grm. Can we regard this latter transition as $2Fe_3 \longrightarrow 3Fe_2$?

The small thermal evolution at A_2 favours the view expressed above that the transformation involves a molecular regrouping, similar to that occurring in the ordinary process of crystallisation, rather than a rebuilding of the atomic structure of the molecule. Hitherto we have not considered a change within the atom itself, such as a variation of the electric or magnetic elements. Some such change must occur in the iron atom, as it enters into different chemical combinations, otherwise how can we explain why iron carbonyl, $Fe(CO)_4$, is diamagnetic, while ferrous chloride, $Fe(Cl)_2$, is strongly paramagnetic? Do we not here have a kind of atomic allotropy? In this sense the allotropic theory may be consistent with the carbide theory which attributes the properties of carbon-steels to definite compounds of iron with carbon (such as cementite (Fe_3C)). Magnetic phenomena appear to be so definitely related to the atom that the existence of different types of iron atom is suggested inevitably, and the suggestion would not be at variance with modern views of atomic structure. Many arrangements of electronic orbits in dense atoms are theoretically possible.

The work of Prof. W. H. and Mr. W. L. Bragg must be considered in relation to any phenomenon of crystals. They have shown the difficulty, even in ordinary cases, of even defining the molecules of the crystals, although in many cases this is possible. But to determine by their method whether, in an iron crystal, any atom has a *special* relation to one of those surrounding it, would be nearly impossible. The optical effects which they investigate are determined only by the nucleus or core of the atom, and the outer arrangements in the atom, determining its allotropic forms, might differ considerably without being capable of detection except perhaps by their magnetic properties. On these lines, therefore, no immediate objection to the existence of such different types of atom

[1] *Vide* Muir and Wilson, "Elements of Thermal Chemistry," pp. 250–53, for many other examples.

can apparently be raised, and the suggestion of atomic allotropy appears worthy of development as a possible interpretation of others among the phenomena of pure iron, which considerations of space have excluded from the present summary.

During the discussion several interesting slides showing variations of the micro-structure of iron were exhibited by Prof. H. C. H. Carpenter.

PREVENTIVE MEDICINE IN PENNSYLVANIA.[1]

PREVENTIVE medicine is a science so likely to appeal to the genius of the American people that it is of considerable interest to read the reports issued in July, August, and September of 1914, by the Pennsylvania State Department of Health on various aspects of its activities.

As elsewhere, so in the State of Pennsylvania, the force which caused the development of preventive medicine was the compulsion exerted by outbreaks of disease. An epidemic of typhoid fever in 1885 was the means of obtaining the enactment of a previously twice defeated Bill to establish a State Board of Health, which, however, at first was much circumscribed in its powers and duties. A severe outbreak of smallpox in the years 1901–04 impelled the Legislature to establish a State Department of Public Health.

At its head is a Commissioner of Health, with very great powers of initiative, on whom falls the duty of appointing whatever assistants he may find necessary to carry on the work. The State Department of Health has direct executive control over all public health problems of every sort in the more rural portions of the State, comprising four-fifths of the land area and one-quarter of the total population. Over the remainder of the population, aggregated in the more densely populated townships, which are required to maintain their own local boards of health, the State Department of Health has advisory and supervisory control, but no executive responsibility except in relation to sanitary engineering, tuberculosis, and the collection of vital statistics.

The State administrative machinery, therefore, in some respects resembles, but in others is in marked contrast to, that of an English county health department. Both have general supervisory and advisory duties with regard to the smaller areas within their compass. The English county department has, however, nothing approaching to the wide general executive functions of the Pennsylvania State Department, although in some respects—for example, in the control of tuberculosis—their activities are akin. The complete responsibility of the Pennsylvania State Department for the health of the public in the rural portions of its area has no analogy in county administration in this country. The English system is based far more than is the Pennsylvanian on local as opposed to central administration.

The organisation of the State Health Department would appear to be on very effective lines. Out of the central department have crystallised a number of sub-departments, or divisions, dealing respectively with vital statistics, school medical inspection, sanitary engineering, tuberculosis dispensaries and nursing, sanatoria, housing, laboratories, and the distribution of biological products. The chief of each division reports directly to the health commissioner. There are two special divisions, one of which conducts all the auditing and accounting and part of the purchasing for other divisions, while the other attends to the whole of the storage and shipment of materials. The divisional executive officers are thus left free to devote their energies to the more essential public health work.

1 Pennsylvania Health Bulletin, July, August, September, 1914.

Comparison of the work of some of these divisions with that of health departments in this country is instructive. For example, the registration of births and deaths is far more closely bound up with public health in Pennsylvania than is the case in England and Wales, in which it is not in any way directly controlled by the Health Department; whereas in Pennsylvania, on the contrary, the Division for Vital Statistics, a branch of the State Health Department, under the direct supervision of a health officer, is responsible for precisely the same work as is done by our local and central registrars in respect of births and deaths and marriages.

In the same way the school medical service, instead of being, as is unfortunately the case in this country, a separate service affiliated only for reasons of convenience to the public health service, is recognised in Pennsylvania as essentially a branch of public health, and as such is administered by the State Health Department through a division of medical inspection. Sanitary engineering, again, carried out as it is by a special division of the State Health Department, is much more clearly recognised as a function of public health than is the case in this country.

Perhaps the most striking feature of the Pennsylvanian scheme is its systematic educational campaign. All reports sent in from every division of the Health Department to the Health Commissioner are dealt with from their public health aspect, and are then handed over to an educational section of the central department, where they are rewritten and issued in popular form as lectures, circulars, leaflets, newspaper talks, or periodical bulletins. This eagerness to popularise technical knowledge is an important side of public health work, which could with advantage be better developed in this country. In general administration, probably English methods give as good results, though possibly in more circuitous ways. Pennsylvania has had the advantage of beginning at a time when it could develop its public health system at one stroke and as a whole, and so could largely avoid the errors and vagaries of a system which has grown by accretion.

H. P. N.

CHEMISTRY AT THE BRITISH ASSOCIATION.

ALTHOUGH so many topical subjects were, on account of the war, excluded from the discussions of the section, the attendance at the meetings was on the whole satisfactory, exceeding the anticipations of the earlier part of the year. It is, however, clear that anything like general interest can only be evoked in the Chemical Section by discussions on rather broad subjects, papers giving the results of researches on some particular branch being only too frequently delivered to nearly empty benches. This not infrequently arises from the paper being so specialised that the author is practically the only person in the room capable of appreciating its significance and value. One cannot help feeling that the atmosphere of the Chemical Society or other specialised body would be more sympathetic. Under the exceptional circumstances of this year foreign guests were few in number, but the section had the pleasure of welcoming and listening to two of our Belgian allies—Prof. Henry and Prof. Ranwez, from Louvain, the former giving an account of researches on the preparation and properties of vinylacetic nitrile, which he has carried out in Prof. Perkin's laboratory at Oxford during his residence in this country, while the latter contributed a paper to the discussion on smoke.

The section met on three mornings and two afternoons, so that although the whole meeting was shorter than has hitherto been customary, chemists actually devoted more time to the consideration of their subject, and the usually rather risky experiment of afternoon sessions proved entirely successful, chiefly no doubt because social counter-attractions were absent.

Two mornings were occupied by discussions, one dealing with smoke and its prevention, the other with homogeneous catalysis. Manchester, to the residents in the rural parts of these islands, shares with Sheffield an unfortunate reputation for griminess; therefore the discussion on smoke was peculiarly apposite. Though many efforts are made to combat the smoke evil, not only because of its noxious effects, but also because of the enormous waste due to the huge quantities of valuable fuel constantly being poured into our atmosphere, much still remains to be done towards the economic utilisation of our fuel supply. The discussion was opened by Mr. E. D. Simon, chairman of the Manchester Air Pollution Advisory Board, with a paper on "Lines of Research in Smoke Abatement." Briefly, it may be said that it is only by a systematic investigation of the amount of deposit, its nature, and the diminution of light caused by the smoke cloud at different observing stations near our great cities, that the damage done can be evaluated and the origin of the smoke determined.

Though factories and works contribute greatly to the nuisance, the domestic chimney, so dear to the Briton, appears to be the offender most capable of correction, by the use of gas fires, coke fires, and semi-coked coal. Mr. Simon put forward the plea that the British Association should appoint a committee to co-ordinate the work of local municipal committees who are prosecuting research on the most efficient forms of domestic heating and the economical and smokeless use of fuel in general.

The position, so far as Manchester is concerned, was further explained by Mr. Haldane Gee and Prof. Knecht, the former reviewing the work carried out in Manchester during recent years, and the latter giving an account of Manchester smoke from the chemical point of view.

Prof. Wynne gave a number of statistics for the city of Sheffield based on an investigation of the rain-water collected in various soot gauges, from which it appears that if the district where the armament works are situated be excepted, the results for the other portions of the city show a remarkable approach to uniformity independent of the direction of the prevailing wind. If the contribution of house fires to the air pollution can be based on the proportion of tar and ammonia collected in the rain-water, no material difference could be traced between the winter and summer six months.

The effect of smoke on vegetation was considered by Prof. Ranwez and Mr. Ruston, the first describing the more general effects on trees and plants, while the second paid special attention to the reduction of sunlight, action of acids on leaves, soot formation, enzyme, and bacterial action. Smoke pollution is apparently an inhibitor of the enzymic chemical changes which occur in plants, and consequently near cities our plants are less bright, form less reserves, and produce seeds with diminished germinating capacity and energy, all which is but too apparent to the gardener in our urban districts. The electrical precipitation of smoke also came in for comment, and some slides shown by Mr. Vernon Harcourt incidentally illustrated well the possibility of combining economic fuel combustion on a domestic hearth with the artistic merits of the English fireplace, a point too infrequently considered, but most of the other speakers were concerned with the necessity for taking some action, compulsion if necessary, to force the inhabitants of this country to be more economical in fuel.

The outcome of the whole discussion, which in many ways was supplementary to that at the Birmingham meeting, was that a committee to consider the whole question of the economic use of fuel and smoke prevention was appointed by the Chemical Section.

The discussion on homogeneous catalysis was opened by Prof. Lewis, who advanced a new theory based fundamentally on Planck's quantum hypothesis. The physical idea underlying the theory is that ordinary or "thermal" reactions are due to the infra-red radiation which is necessarily present throughout any material system in virtue of its temperature. When a reaction proceeds without the addition of a catalyst, it is to be inferred that the density of the radiation "naturally" present in the system is sufficient to activate the molecules taking part in the reaction. Each type of molecule has its own characteristic absorption and emission bands in the infra-red, and can only be activated chemically by the absorption of radiant energy the frequency of which corresponds to one or more of these band positions. The function of a positive catalyst is to increase the radiation density of the frequency which corresponds to that of the reacting substance, a negative catalyst reduces the energy frequency of the "useful" frequency, and so hinders the rate of decomposition of the substance. By applying Planck's quantum theory to the simple case of a mono-molecular reaction Prof. Lewis deduced the following expression for the variation of the velocity constant (k) with the temperature (T):—

$$\frac{d \log k}{dT} = \frac{Nh\nu}{RT^2},$$

where N is the number of molecules in one gram-molecule, h is Planck's constant, R the gas constant per gram-molecule, and ν the characteristic infra-red vibration frequency of the reacting substance. By the aid of this expression values for ν can be calculated from temperature coefficient measurements. From measurements on the inversion of cane-sugar and hydrolysis of methyl acetate it was calculated that ν corresponded to a wave-length $1{\cdot}2\ \mu$ and $1{\cdot}9\ \mu$ values in fair agreement with the absorptions determined by Coblentz from transmission spectra. Prof. Lewis suggested that as aqueous hydrochloric acid possesses a band in the same region, its known positive catalytic effect is due to this cause, as also the catalytic effects due to pure and mixed solvents.

By considering that only those molecules react which reach a "critical" condition, namely, one in which they acquire a certain energy in excess of the average energy per molecule in the system, a view put forward by Marcelin in a series of papers on reaction velocity, Mr. J. Rice deduced a very similar expression for the relation of k to T to that given by Prof. Lewis. Considerable forces must hold the molecules together when near each other, but the law of force must be such that at a "critical" distance the attraction must weaken and change to repulsion, thus implying that the potential energy between two molecules is greatest at the critical distance apart. By assuming that the forces involved are electromagnetic and subject to modification due to the changes in radiation density produced by the catalyst, results are obtained in agreement with the existing experimental data.

Prof. F. Francis exhibited and described an apparatus for measuring the velocity of catalysis of nitrosotriacetonamine and allied derivatives by hydroxyl ions, based on the determination of the pressure of the nitrogen evolved. The method was also of use to determine the concentration of the hydroxyl ions. He also described the curious effect of neutral salts, and pointed out that nearly the same quantitative retarda-

tion of the velocity is produced in some cases by chlorides and hydroxyl ions. Small concentrations of sulphates produced an acceleration. Prof. Francis pointed out that the order in which the salts effected the velocity constant was that found in the lyotropic series, iodides producing the greatest and chlorides the least effect.

Dr. N. V. Sidgwick pointed out that while Prof. Lewis assumed the catalytic activity to be proportionate to the amount of catalyst, this was not always true, and further that temperature coefficients of isomeric changes and mono-molecular changes in general are abnormally high. The immediate need before proceeding to theory is an accumulation of more exact experimental data.

Prof. E. C. C. Baly from spectroscopic observations considered that as the first step in a chemical change must be the conversion of the reacting substance into an intermediate very reactive state, a positive catalyst must be an agent which converts more substance into this state. This intermediate state results from the introduction of a definite amount of energy. He suggested that probably the actual amount of energy thus needed was constant and independent of the value of the vibration frequency, and that the numbers of energy quanta necessary to produce the critical increment at any given vibration frequency of the molecule are numerically related to one another. Further, the relation between the active and inactive forms does not obey the law of mass action.

It may be fairly concluded from the discussion that far more experimental data must be accumulated, particularly as regards temperature coefficients and changes of velocity with increasing amount of catalyst.

Other parts of the mornings were occupied with several short papers, of which space will only permit the titles. Dr. H. F. Coward and Prof. A. Harden described and exhibited some lecture diagrams used by Dalton in illustration of his atomic theory; Dr. A. Hynd, "Configuration in the Sugar Group"; Dr. H. J. S. Sand, "A New Cadmium Vapour Arc Lamp"; Dr. Robert Mond, "Ruthenium Di-Carbonyl"; Dr. W. E. S. Turner, "Ionisation in Solvents of Low Dielectric Constant," and, jointly with Mr. J. D. Cauwood, "The Molecular State of Salts in Solution."

On one afternoon Prof. W. J. Pope gave an experimental lecture on liquid crystals, and on the other Prof. W. A. Bone, Prof. H. B. Dixon, and Dr. H. F. Coward contributed papers on combustion and explosion of gases with some experimental illustrations.

The account of the work of the section would not be complete without a word about the discussion on isotopes, which took place in Section A, but which was peculiarly interesting to chemists. The discussion is summarised in the report of the proceedings of Section A in NATURE, but results obtained by Dr. Whytlaw Gray from microchemical experiments showed that certain salts, iodides, chlorides, chromates, etc., of the product of decay of radium emanation are identical as far as solubility, crystalline form, etc., with the corresponding salts of lead. Approximate determinations of their melting points also indicated identity. To the chemist this is perhaps more convincing than a volume of deductions by a physicist.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

THE president of the section, Major Lyons, was unable to be present, owing to pressure of work in connection with the war, and his address, the main part of which was printed in NATURE of September 23, was read by Mr. H. Yule Oldham. His other duties were undertaken by the vice-presidents, Mr. G. G. Chisholm, Prof. J. W. Gregory, Mr. Harry Nuttall, and Mr. H. Yule Oldham.

On Wednesday morning Mr. A. R. Hinks gave an account of the map which is being compiled at the Royal Geographical Society under the direction of the General Staff on the scale of 1 : 1,000,000. After a brief statement regarding the inception and progress of the map, and the principles upon which it is being compiled, he referred in more detail to various methods of showing relief, the selection of names, the index to boundaries, and marginal names. Mr. B. C. Wallis followed with a paper on methods of representing the distribution of population upon maps, and more especially upon the maps already described by Mr. Hinks. Taking the Buda-Pest sheet, he showed how the population in each administrative area might be assumed to be evenly distributed throughout, and how the density when located in the centre of the area might be treated in the same way as a spot height in contouring. He also showed maps, and discussed methods for the representation of the various ethnic elements in the population.

Wednesday afternoon was devoted to a series of short papers by members of the section who had been present at the Australian meeting. Mr. O. J. R. Howarth compared several well-known maps showing the distribution of vegetation in Australia, and pointed out the great discrepancies which existed between them. He suggested that a committee might at some suitable time be appointed to examine and criticise the material upon which distributional maps in general are based, and that such a committee might begin its labours by a consideration of the material available for the construction of vegetation maps of Australia.

Prof. J. W. Gregory discussed the relations of the central lakes of Westralia, which he believes to be basins left by the dismemberment of a Miocene river system. He considers that the drainage from lakes Giles, Barlee, and Ballard originally passed through Lake Raeside south-eastward to the sea, and that the channel from Lake Ballard south-west through Lake Deborah to the Swan River, indicated on a recent contour map of Western Australia, was of later date and was formed by the blocking of the south-eastern outlet by wind-borne drifts.

Mr. J. McFarlane described the Burrinjuck Dam and the Murrumbidgee irrigation area in New South Wales, with special reference to the interaction between man and his environment in an irrigation area.

Mr. H. Yule Oldham explained the various stages in the explorations by which the outline of the Australian continent had been filled up.

Thursday morning was devoted to joint discussions with Sections C and H respectively. The discussion with Section C on the classification of land forms was opened by Dr. J. D. Falconer, who proposed to set up two classes of land forms, each containing two orders :—

Class A, endogenetic forms: Order I., negative forms; Order II., positive forms. Class B, exogenetic forms: Order I., degradation forms; Order II., aggradation forms.

The two orders of endogenetic forms are then subdivided into four families :—

Family 1. Forms due to superficial volcanic activity.
2. Forms due to sub-crustal volcanic activity.
3. Forms due to radial movements.
4. Forms due to tangential movements.

Similarly, the two orders of exogenetic forms are each subdivided into nine families :—

Family 1. Forms due to the action of the run-off
2. Forms due to the action of percolating water.

3. Forms due to the action of streams and rivers.
4. Forms due to the action of life.
5. Forms due to the action of lightning.
6. Forms due to the action of sun-heat.
7. Forms due to the action of the atmosphere.
8. Forms due to the action of frozen water.
9. Forms due to the action of the sea.

Each family is then subdivided into genera and species or specific forms.

In the discussion which followed, Prof. Gregory said that the initial difficulty lay in the fact that different classifications were required by geography and by geology. Dr. Falconer had restricted the term land-form to what may be called the simple land forms, whereas the term was originally used for the greater features which may be called compound land forms. The geographer needs a classification which is based more on form than on origin, and uses familiar terms, such as mountain and valley, with the help of which he cannot afford to dispense. At the same time, Prof. Gregory thought that Dr. Falconer's classification would be of great value as a complete systematic tabulation of land-forming processes. Prof. Grenville Cole said that a systematic classification of land forms might tend to check the descriptive faculty of the teacher. Brief but comprehensive description in language familiar to the reader or hearer was needed to bring home the relation of surface features to man's life among them. Close definition, especially in the Greek language, might tend to obscure the beauty of a landscape. Mr. G. G. Chisholm considered that the distinctive feature of geography was the study of the influences of terrestrial local conditions and place relations. For this, of course, description was necessary, but he failed to see the utility for geographical description of the subdivisions of simple land forms proposed by Dr. Falconer.

The discussion with Section H on Racial Distribution in the Balkans was opened by Prof. G. Elliot-Smith. An account of it will appear under the proceedings of Section H.

In the afternoon a paper was read by Mr. P. M. Roxby on North China and Korea, in which he embodied many of the observations he had made in these regions during his tenure of an A.K. fellowship. He dealt principally with the railway situation, the relations of China to Russia and Japan, China's interest in the European war, and the work of the Japanese in Korea. The paper was illustrated by an exceptionally fine set of lantern-slides. Dr. R. N. Rudmose Brown followed with an account of the political and economic position of Spitsbergen at the outbreak of war. He also explained the results obtained by Dr. W. S. Bruce's expedition there in 1914.

On Friday, the first business before the section was the consideration of the report of the committee appointed to inquire into the choice and style of atlas, textual and wall maps for school and university use. Thereafter a paper was read by Mr. Raymond Curtis on the distribution of population in the district round Leek, in which he showed how in the agricultural area the village nucleus of farmhouses might develop in turn into the inn-village, the shop-village, the fair-village, and the market-town. Mr. C. B. Fawcett discussed the development of the middle Tees and its tributaries. He considered that the river system as a whole is in a comparatively early stage of development, but that it is the product of at least three distinct cycles of erosion. The morning sitting concluded with a paper by Prof. H. J. Fleure on the distribution and movement of population in South Britain in early times. In Neolithic times the chief areas occupied in England were the chalk downs, the moorlands of the south-west, the Cotswold top, a few patches, especially near Birmingham, in the Midlands, some valleys in the East Anglian Chalk, as well as a few chalk ridges, *e.g.* above the Fen edge, the Pennines, moorland tops in South Wales, etc. Descendants of the dark, long-headed Neolithic folk who occupied these uplands are still found in the valleys around them, except that they have been nearly washed out along the Chalk in the south, which has been the scene of many invasions. The valleyward movement of people in Britain is therefore of great importance, and evidence was given of its various stages and sociological results.

The proceedings of the section concluded on Friday afternoon, when Prof. Patrick Geddes read a paper on the study of cities, and at its conclusion conducted a party over an exhibition arranged by himself and Miss Barker of maps, pictures, books, and broadsheets illustrating the war, and of regional surveys illustrating the geographical and historical growth of cities.

JOHN MCFARLANE.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

LONDON.—A memorial service for members of the University who have fallen in the war was held at the Temple Church on November 1. The service was conducted by the Master of the Temple, assisted by Bishop Hine and the Bishop of London. The Bishop of Kingston was the preacher. Included in the list of the 250 graduates and students commemorated are the forty-two from University College, thirty from King's College, eighteen from the Royal College of Science and the Royal School of Mines, sixteen from the City and Guilds College, seventeen from the South Eastern Agricultural College, seventeen from St. Bartholomew's Hospital, fourteen from Guy's Hospital, nineteen from London Hospital, and eleven from St. Mary's Hospital.

It is understood that the appointment of a Principal to succeed Sir Henry Miers is to be postponed.

The first list of students serving in the war, to whom honorary war degrees have been granted, has been published.

OXFORD.—The Vice-Chancellor's choice of a Romanes lecturer has this year fallen on an Oxford resident, viz., Prof. E. B. Poulton, Hope professor of zoology. The subject chosen, "Science and the Great War," is one to which Prof. Poulton is known to have given great attention. For many years past he has lost no opportunity of advocating an increased attention to the results of scientific research in relation to all forms of national activity, whether warlike or peaceful, and he has consistently deplored the indifference to the lessons of science displayed by most of our leading politicians and statesmen. A valuable and interesting utterance on his part is confidently looked for. The lecture will be delivered at the University Museum, on Tuesday, December 7, at 3.30 p.m.

IT is stated in the *Pioneer Mail* of October 9 that on October 1 the Bill to establish and incorporate a teaching and residential Hindu university at Benares was passed into law. Now that the Bill has been passed, the promoters are about to address themselves to details connected with the institution. The Viceroy will lay the foundation-stone early in February. It is hoped that the work of the University will be entered upon by July next, though, of course, at first on a limited scale.

THE calendar for the present session of the University of Sheffield provides an excellent example of the numerous directions in which a modern university succeeds in meeting the needs of the area in which it is situated. The industries of the Sheffield district are reflected in the degrees in applied science which the University is prepared to confer. Students may take courses in preparation for the degrees of bachelor, master, or doctor in engineering science, or in metallurgy. In both these subjects, too, considerable specialisation is encouraged. The examinations of the University admit to associate membership of various professional institutions, and are also recognised by certain Departments of State. The University grants a diploma in domestic science. A two years' course of work in the University and the Sheffield Training College of Domestic Science has been arranged. The scientific portion of the course will be taken at the University, and the technical work in cookery, laundry, and housewifery at the training college. The calendar also provides full information of a well-planned University extension scheme which has been developed, and of numerous flourishing university societies. At the same time the more usual University work is carried on in the faculties of arts, pure science, medicine, and law, concerning which detailed particulars are given.

THE abridged calendar for the current session of University College, University of London, has been received. Detailed guidance is given as to the courses which should be taken by students proposing to graduate in one of the faculties of the University. The calendar points out that facilities for post-graduate work and research are provided in all departments of the college. There is a large science library in which the books concerned with the various scientific departments are grouped. The library contains all the most important scientific periodicals (British and foreign). The particulars of the studentships, scholarships, fellowships, and prizes for research awarded by the college run to forty-eight pages. The list of original papers and other publications from the various departments of the college since the provost's report in last year's calendar fills fourteen pages, and is good evidence that the reputation of the college as a centre for research is being worthily maintained. In his report, printed in the calendar, on the work of the last session at the college, the provost said the benefactions of the year had inevitably been fewer than usual, but he was able to announce that upwards of 1100*l.* had been added to the fund for the new chemical laboratories. He said a further sum of between 800*l.* and 900*l.* was needed for the partial minimum equipment for this session. The equipment necessary for the new physico-chemical laboratory is of a special and expensive character, and will cost about 10,000*l.*

THE calendar for the present session of the University College of North Wales has been received. Students of the college prepare for degrees of the University of Wales, which have been so framed as to allow great freedom in the choice of subjects of study. Each degree in arts or science may be regarded as a certificate of the preliminary knowledge required at matriculation, and of subsequent study pursued at one of the constituent university colleges for a period of three years, and tested at each stage by university examinations. Advanced study is encouraged not only by the existence of advanced and honours courses, but also by the regulations for the higher degrees, and by the award of university fellowships and studentships for research. As an instance of the encouragement given to research we notice the calendar states the professor of mathematics is glad to furnish subjects for research in applied mathematics to candidates who have acquired a substantial knowledge of the subject-matter of the honours course and to direct their work. A number of aeroplane problems are generally available. In the agricultural department of the college, students may prepare for degrees in agriculture and rural economy or for the college diploma in agriculture, and their practical work is assisted by the facilities provided at the college farm of 675 acres. With the aid of a grant from the Development Fund, well-equipped laboratories have been provided, and full facilities are now available for the investigation of problems submitted to the department.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 26.—M. Ed. Perrier in the chair.—G. **Bigourdan**: Astronomical observations made in France before the foundation of the Academy of Sciences. An outline of the life of Fabri de Peiresc (1580–1637).—H. Le **Chatelier** and B. **Bogitch**: The preparation of alkaline nitrates starting with calcium nitrate. The preparation of ammonium nitrate by the interaction of calcium nitrate and ammonium sulphate presents difficulties on the large scale owing to the pasty mass being nearly impossible to filter. After heating under pressure in a closed vessel to 150° C., the calcium sulphate forms larger crystals, and the ammonium nitrate can be readily removed by washing.—Fréd. **Wallerant**: Some crystallographic peculiarities of aniline nitrate. This salt is dimorphous, with a well-marked transition point at 97·6° C.—Henryk **Arctowski**: Variations in the ratios between faculæ and sun-spots.—Luc **Picart**: A criterion for the identification of the minor planets.—Ernest **Esclangon**: The quasi-periodic integrals of a linear differential equation.—A. **Angelesco**: Associated polynomials with several variables.—St. **Procopiu**: Electromotive force due to motion. A study of the electromotive forces set up in a symmetrical cell (metal-electrolyte-metal) by motion of one electrode or of the electrolyte.—A. **Guilliermond**: Some cytological observations on the mode of formation of anthocyanic pigments in flowers.—G. **Rivière** and G. **Bailhache**: *Amygdalopersica formonti.* An account of some peculiarities in the growth of an almond grafted on to a peach tree.—Th. **Guilloz** and E. **Stock**: A compass for the location of metallic fragments in the body.—E. **Vasticar**: The structure of the auditory cell.—F. **d'Hérelle**: The biological method for the destruction of locusts. Details of an improved method for utilising the *Coccobacillus acridiorum* for the destruc- of locusts.—E. **Aubel** and H. **Colin**: The reaction of the medium and filtration of toxins.

CO-OPERATION IN SCIENTIFIC RESEARCH.

THE principal part of all scientific discovery and research in past time has been the result of private or individual work. Men of great originality and genius have struck out new lines of thought, or made epoch-making discoveries in moments of inspiration. Men of lesser originality, but painstaking workers, have contributed to knowledge by careful measurements or patient observations. In many cases useful partnerships of two or three have been established, in which the members have shared the labour and each contributed something the other lacked. In the early days of research, when the means of investigation in laboratories or apparatus were limited, only those who possessed in a high degree the capacity for discovery found or made opportunity to carry on such work and secure publication for it. At the present time, when laboratory accommodation is extensive and the numbers of the workers greatly multiplied, the difficulty is rather to find new subjects for research than the means wherewith to do it.

The result of this is seen in an enormous increase in the amount of published scientific memoirs, and in the disconnected nature of much of it. The Proceedings of our learned societies, from the Royal Society downwards, and of the technical institutions as well, are a record of an ever-increasing number of papers on subjects, for the time being, attracting attention, but which are quite detached in their manner of dealing with it. Take, for example, such topics as radio-activity, electric waves or oscillations, ionisation of gases, wireless telegraphy, radiation, and many other popular fields of research, and consider the enormous number of papers describing experiments on these subjects which have been published during the last twenty years. We have here the product of much arduous labour on the part of an army of scientific workers. Certain discoveries and papers stand out as landmarks and epoch-making. On the other hand, it is impossible to avoid asking the question whether much of the work of those who may perhaps be described as the privates and officers of lower rank in the scientific army could not have been made to yield more valuable results if it had been better co-ordinated and directed.

In no class of work involving many workers can we dispense with organisation. An army is not a collection of armed individuals. It is a machine in which each man is an element, with place and duty. An effective and successful commercial institution, such as a railway company, is a complicated organism, and not a multitude of persons, each playing for his own hand. The present method of conducting scientific research is a go-as-you-please method, in which each man does what his own inclinations suggest to him or the means at disposal allow him to do. It is perfectly certain that, as the result of this war, the British Empire will have forced upon it in all departments of activity, first, greater economy in the use of materials; secondly, greater efficiency in the workers; and, thirdly, greater demand for value in the result. We have to get rid, in every department of work, whether politics, commerce, manufacture, or domestic life, of waste, inefficiency, and make-believe or valueless products. We have to get rid of them in scientific research as well.

This can only be done by limiting the individual initiative and adopting greater and more carefully thought-out co-operation. It is well, therefore, to begin to consider the lines on which these reforms shall proceed. In the first place, they must begin at the fountain head. We must ask for greater effectiveness and more valuable results from the learned societies, because these represent the tendencies and ideals of the leaders of science. The Royal Society was originally founded to stimulate and encourage scientific investigation into natural phenomena, and its analogue in the technical realm, the Institution of Civil Engineers, to promote the utilisation of the forces and energies of nature for the use and benefit of mankind. Whilst these great objects are undoubtedly assisted by the facilities offered by these societies for the publication of accounts of new knowledge or new achievements, one great purpose which perhaps they might much more adequately fulfil should be to point out and direct the forces and energies of research in new and useful channels.

There is one way in which this might be done, and that is by carefully organised discussions on definite large problems and questions lying at the boundaries of our knowledge. The usefulness of the British Association meetings has been greatly increased of late years by such general discussions, as a result of much criticism by Sir William Tilden, Prof. H. E. Armstrong, Sir Oliver Lodge, and others.

Why, then, should not the Royal Society devote several meetings during the session to general

discussions, with careful prearrangement, having for their special object to elucidate the present state of knowledge on some particular subject, to define its unsolved problems, and suggest or indicate the most fruitful lines for future research and discovery? To such discussions eminent workers in the subject, even though not fellows, should be invited. The object should be to direct individual workers to lines of investigation converging in certain useful directions.

The example would then doubtless be followed by other societies; indeed, the Faraday Society has held several successful meetings of this kind. The function of such meetings should be to stimulate the thoughts and originality of the adult investigators, just as the teaching of a good teacher does for his students. Then, in the next place, valuable work might be done by the formation in these societies of committees of investigation, composed of small groups of members or fellows charged with the special duty of following out some particular line of experimental or theoretical work, and publishing the result as the joint work of the committee, and not of individual members of it. Such committees have often been formed and done much valuable work, and it suffices to mention the British Association Committee on Electrical Units to recall one of the most famous of them, and the Engineering Standards Committees of the Institution of Civil Engineers.

At the present time, members of learned societies either sit and listen to abstracts of papers read by others or read one of their own, but they seldom, if ever, find the opportunity of joining hands in a piece of joint work to which all would contribute an effective share. There are many fields of investigation in which the work of the mathematician, the physicist, the chemist, and perhaps the engineer could be united with great advantage, and far more valuable work done if each member of the partnership were to play for the team than simply for his own hand.

The mathematician is apt to direct his attention too much to problems in which the technique of his science is involved, and too little to the function of co-operating with experimental research in bringing us to fresh discovery. In like manner, the experimentalist may have his skill more rewarded if directed by the guidance of the mathematician, who can point out to him the best direction in which it can be utilised.

No doubt such co-operative work requires an amount of self-suppression which is not widely distributed, but it is what every public-school boy exhibits who plays cricket or football for his house and not for himself, or every soldier or sailor who puts "The Service" before everything concerning his own life and interests. Then the same thing applies to commercial research. Every British manufacturer who affords himself some small degree of scientific research in his business is anxious, before all things, to keep his difficulties and knowledge to himself. If he could be induced to see that his real foes are, not his own kindred, but the highly organised German manufacturers, perhaps he might be inclined to listen to suggestions for co-operative research maintained by common effort in the common interest. There are in all manufactures scientific problems which all concerned are interested in solving. These could probably be better dealt with by a strong and highly competent scientific staff maintained in common than by insufficient individual effort.

In this matter, however, we work in a vicious circle. Until the manufacturers recognise that sufficient inducement must be offered to the highest scientific ability to enter commercial service, the best men will not take up the work, and until such highly trained men with initiative are proved to be available, the manufacturers are sceptical as to the advantages of scientific assistance. Nevertheless, the supply will create the demand, and it is the duty of the universities and technical colleges to see that the training they provide turns out first-class, and not only second-class, men.

The Advisory Council concerned with the Organisation and Development of Scientific and Industrial Research should have all these matters in review. We stand at the entrance to a new era in the life of the world, and it is imperative that we should all look the facts fairly in the face, and realise that we have to attain in every department of national life a higher efficiency and more effective service for the common good.

SCIENCE AND ART OF ILLUSTRATION.

The Essentials of Illustration: a Practical Guide to the Reproduction of Drawings and Photographs for the Use of Scientists and Others. By T. G. Hill. Pp. xii+91. (London: W. Wesley and Son, 1915.) Price 10s. net.

If too little importance has been hitherto attached by the writers of scientific books to the way in which they have been illustrated, it is due to various causes, not the least of which is the want of guidance as to the manner in which pictorial illustrations are produced. Want of skill

in draughtsmanship, and want of artistic perception in the selection or arrangement of subjects, no doubt account for some of the shortcomings of illustrated scientific works. But beyond these causes there exists a third, unfamiliarity with the technical processes employed in the manufacture and printing of illustrations of different kinds. Drawings made with the pencil, the pen, or the brush require each of them a different treatment from that which is appropriate for photographs. The arts of copper-plate etching, of dry-point etching, of mezzotint, of wood-engraving, steel-engraving, lithography, and aquatint are each marked out for special preferences in particular cases. In the case of photographic reproduction the processes of photogravure, collotype, half-tone block making and line block making have each their own particular advantages; some are better for one subject, or for one kind of book, and others for other subjects or books. And this quite apart from any of the more complicated questions of reproduction in colour.

The volume before us is a brave and not unsuccessful attempt to guide the scientific writer, and to put into his hands a manual which in clear and simple language reviews the various means by which book illustrations are made, whether by hand or by camera, and converted into printed pictures. The author, who is a professed botanist and an accomplished artist to boot, possesses a wide acquaintance with the art of book illustration, and his references to leading works in which the pictures are produced in different ways are copious and appropriate. He is as much at home with the delightful wood-cuts of the old herbals of Fuchsius and Matthiolus as with the hand-coloured copper-plate engravings of Sowerby or the plates in the *Philosophical Transactions*. But for scientific workers other than botanists it will be tantalising to find that for examples of different kinds of illustration a majority of the references are to the volumes of botanical serials or to inaccessible and obscure botanical monographs. The abundance of excellent illustrations, nearly all original, including twelve plates and thirty-eight text-figures, goes far to atone for this defect.

Our author discusses his subject under the three headings of intaglio printing, plane surface printing, and relief printing. He deals with the first section in eleven pages, in which brief compass he includes technical descriptions of the processes of line engraving, etching, soft-ground etching, mezzotint, and photogravure. The instructions are too brief to be taken as working guides for the practice of the respective arts, but may serve to enable intelligent readers to recognise the process by which any particular illustration has been produced. Under the title of "Plane Surface Printing," a large amount of space is rightly devoted to lithography, though for the successful employment of this process a degree of craftsmanship is necessary to which few scientific book-writers can ever attain. Chromolithography is dismissed very briefly, as are photolithographic processes also; while more attention is given to collotype, a process which except in the hands of professional craftsmen is seldom satisfactory. Under the heading of "Relief Printing" are grouped the topics of wood-cutting and wood-engraving (of which arts the author wisely omits all technical instructions), the half-tone photo-mechanical process, the half-tone three-colour process, the production of photomechanical line-blocks, and the swelled-gelatine process. The survey is not quite comprehensive; it does not include the useful, if little used, process called "monotype" or "electrotint," which is one of the easiest for amateurs. It does not mention the excellent tungstate of lead process for line-blocks used by Messrs. Walker and Boutall. Neither does the author refer to the use of a process, common in the production of postage-stamps, of surface-printing transferred from an original that was engraved on copper or steel.

Probably the most useful parts of the work will be the passages intercalated between the descriptive matter, in which the author gives admirable advice to the writers of scientific papers on the preparation of their illustrations, on methods of drawing for reproduction, whether of line-diagrams, or of microscopic details, of maps, or of graphs. He advises, on the whole, against the use of separate plates, and is in favour of illustrations incorporated in the text, and therefore printed from relief-blocks. Some of the suggestions about spacing out figures on a plate or avoiding the abomination of glazed paper, are, if rather naïve, decidedly apposite. By way of affording comparison between results of rival methods three plates are given, produced from the same photographic negative (a salt-marsh in Brittany) in photogravure, in collotype, and by half-tone block respectively. All are excellent; but the half-tone block is remarkably good.

The recommendations as to drawing for the purpose of reproduction are excellent, but the author should not call the art of "lettering" (so neglected by non-professional draughtsmen) by the name of "printing"; that is exactly what it is not. Very useful hints are given as to the aid to be derived by drawing in waterproof ink upon an ordinary photographic silver-print, which is then bleached out chemically (recipes given for the bleaching agent), leaving a useful line-drawing.

Very useful, too, are the remarks as to the stages, in the various processes, at which corrections may be made. We miss certain references which might be expected. There is no mention of the etched copper-plates of Hooke's "Micrographia" (1665), with its celebrated enlargement of *Pulex irritans*; or of the use of copper-plate etchings printed in the text as in many early books in science; or any reference to the great advantage (if properly printed) of wood-engraved line diagrams with lines and letterings cut in white against a black background, as in the "Œuvres de Verdet," admirably printed about 1870 at the Imprimerie Nationale of France. But the success of these last-named cuts depends essentially upon the quality of the ink used, a weak point with almost every English printing house, as William Morris discovered when he wished to produce the Kelmscott books. For some unknown reason English printers prefer a "grey" to a really fine black printing; and the ink they habitually use would be quite unsuitable for some of the finely-cut blocks which adorn certain recent German text-books of physics. The final chapter on relative cost of blocks and plates is, in spite of some defective arithmetic, commendable.

On page 67 the author makes the comment that drawings of microscopic details, usually produced by lithography, ought not to be so, "since the figures are necessarily divorced from the letter-press." This is an entire blunder. One of the most satisfactory of modern text-books, the "Practical Pathology" of Prof. G. Sims Woodhead, has more than a hundred exquisite illustrations, in two or three colours, printed in the text. The printing of this and other kindred books seems to be an enviable speciality of a firm of Edinburgh printers.

A final word of praise must be given to the manner in which this book is itself produced. The typography is far above the average; and in respect of clear type, wide margins, and clean imposition is a credit to the press from which it issues. The omission of an index is an unpardonable sin, for which the printer is not responsible.

S. P. T.

ABORIGINAL INHABITANTS OF NEWFOUNDLAND.

The Beothucks or Red Indians, the Aboriginal Inhabitants of Newfoundland. By J. P. Howley. Pp. xx+348. (Cambridge: At the University Press, 1915.) *1l. 1s.* net.

THE Beothucks described in this fine monograph, the result of the life-long devotion of Mr. Howley to the investigation of this mysterious tribe, are an ethnological puzzle, and, like that of the Tasmanians, with the scanty material at our disposal it is practically insoluble. In the case of these two races we possess little material save some articles recovered from their graves or camps and the more or less vague and fragmentary accounts of untrained observers.

The Beothucks were relentlessly attacked on two sides: by the Micmacs, an intrusive Algonkin race from the American mainland, and by the French and British hunters and fishers who began to visit Newfoundland when its valuable fisheries became known in Europe.

As in the case of the Tasmanians, the last survivor was a woman, who died in 1829. Before their final disappearance the conscience of the colonists had been aroused to the tragedy of the destruction of a friendless and generally inoffensive people. An institution for their protection was established, and expeditions were sent in search of the survivors, but without much result. One exploring party came into touch with them in 1810, but owing to misunderstandings and some lack of intelligence on the part of the leaders, little was learned about them. We know that they lived in circular or octagonal huts with a fireplace in the centre, round which in a circle of pits the occupants sheltered themselves from the rigours of winter. They were a tall, robust people, dressed in skins, armed with bows and arrows, spears, and clubs. They did not, like the Indian tribes of the mainland, scalp their dead enemies; they cut off their heads and stuck them on poles. Of their religious beliefs we know little. They recognised a life after death, and that the spirit held some sort of communication with the survivors, and they seem to have believed in some greater spirit, like the Manitou of the Indian tribes. They are said to have washed themselves only after the death of their wives, a rite pointing to some kind of belief that the ghost clung to its nearest relative. They used red ochre freely as an ornament.

It is difficult to decide their racial affinities. Some believe them to be connected with the Red Paint people of Maine. A wilder theory represents them as the descendants of Scandinavian ancestors, but this is disposed of by their skull measurements and the scanty vocabularies which survive. They were probably not allied to their nearest neighbours, the Micmacs and the Eskimo, but they may have been a branch of the Algonkins, modified in appearance and manners in their new environment. This migration from the mainland must have been early; otherwise their language would more closely resemble that of the continental tribes.

It is easy to blame the early colonists for the

destruction of this tribe, but for this a heavier responsibility rests on the Micmacs. Mr. Howley's book tells all that can now be discovered about them. Even if it shows lack of literary skill and in some places might have been with advantage abridged, it is an adequate record of a regrettable chapter in the history of the colony. In its format and illustrations it is worthy of the traditions of the Cambridge University Press.

THE RESISTANCE OF SHIPS.

Ship Form, Resistance, and Screw Propulsion. By G. S. Baker. Pp. vii+247. (London: Constable and Co., 1915.) Price 12*s*. 6*d*. net.

THE author of this book is the superintendent of the William Froude experimental tank at the National Physical Laboratory, and it is with the results of model experiments in this and other such tanks that the greater part of the book is concerned. While there is little new material in the book, it forms a valuable collection of collated data in ship form and resistance research, and from this point of view should be useful to the student of naval architecture and to the designer to whom the services of an experimental tank are available. Full reference has been made throughout to the work of Taylor, Biles, Froude, and Peabody. Such research results as the author considers to be of permanent value have been collected and analysed, and although opinions will differ as to the value of much of the great mass of matter which has been ignored, the book shows evidence of much care in sorting and examining published data.

The book is divided into two sections, the first dealing with "Ship Form and Resistance," and the second with "Screw Propulsion." In the first and most successful part of the book, the theory of ship resistance, with its dependence on skin friction and on eddy and wave-making resistances, is first considered. The effect of form and of variations of form on these separate sources of resistance is considered in detail, and much attention has been paid to the analysis of experimental data bearing on this part of the work. Particular emphasis is laid on the importance of the "prismatic" or "longitudinal" coefficient of a vessel, as opposed to its "block" coefficient. Experiment clearly shows that the resistance of a ship, and more particularly the form of its resistance-speed curve, depends chiefly on the longitudinal distribution of its displacement. A large part of this first section of the book is devoted to the effects on resistance of varying lengths of entrance, run, and parallel middle body, work with which the author's own investigations have been largely concerned.

There is a useful chapter on the form and resistance of high-speed vessels of abnormal type, including hydroplanes and the floats of seaplanes, and a further chapter deals with the effect on resistance of varying depths of water and of restriction in the waterway of narrow channels.

The second portion of the book deals briefly with the various theories of the screw propeller; with the elements of screw propulsion; and the design of propeller blades. Screw efficiency, with the allied questions of hull efficiency, wake deduction, and thrust deduction, are clearly explained in a very satisfactory series of chapters. A chapter is devoted to a consideration of the phenomenon of cavitation, and one to a brief sketch of the main engine. This forms the least satisfactory portion of the book. In the chapter on cavitation there is much loose definition and lack of precision, which will probably be rectified in any further edition, while the chapter on the main engine is very superficial. The book would not suffer appreciably by the deletion of this section. The final chapter touches briefly on the tabulation, plotting, and analysis of measured-mile trials.

The book as a whole is well arranged and has a good index.

OUR BOOKSHELF.

Elementary Lessons in Electricity and Magnetism. By Prof. S. P. Thompson. New Edition. Pp. xvi+744. (London: Macmillan and Co., Ltd., 1915.) Price 4*s*. 6*d*.

THIS well-known book has become almost a classic for those beginning the study of electricity and magnetism. It is an encyclopædia of information on all things electrical. A new edition of a volume that attempts so much, in a science which develops so rapidly as electricity, must suffer many changes, and the new volume contains two interesting new chapters—one on wireless telegraphy, and the other on the modern conception of the electron. It is a tribute to Prof. Thompson's skill as an expositor that he deals in a short chapter with such difficult problems as those involved in the consideration of the oscillations in the coupled circuits of a high frequency oscillation transformer. The chapter on electrons is also a welcome addition. The author has managed to compress into a dozen pages as much information on this subject as is usually contained in books of much larger size.

It is a matter for regret that Prof. Thompson has not stated Ohm's law as it is generally understood at the present time. Ohm's law as stated by Ohm, without the condition of unaltered physical properties, is not a law at all. In the text it is stated that the "resistance of a given

conductor is, in fact, constant, *so long as its physical properties are unaltered*," and this is the only meaning Ohm's law can have if it is a law and not a statement without physical significance. But this is a small point to criticise where so much is excellent.

It is as a historian and recorder that Prof. Thompson has earned the gratitude of electrical engineers and physicists as much as in any other direction; and from that aspect alone his "Elementary Lessons in Electricity and Magnetism" is worth reading.

Market Gardening. By Prof. F. L. Yeaw. Pp. vi + 102. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1915.) Price 3*s*. 6*d*. net.

THIS little book is intended to serve not only as an elementary text-book of market gardening, but as an introduction to vegetable-growing in school and home gardens as well.

To attempt to deal with so complex a subject within the space of 68 pages of bold type was heroic, and only an author well acquainted with his subject could have given so much trustworthy information in so small a space. We could wish that its admirable points had been still further elaborated for the use of beginners, who are assumed to know more of manual processes than is likely to be the case.

Viewing it as an account of American market gardening, one is struck with the remarkable omissions concerning things which we believe, on this side of the Atlantic, to be of the first importance. Intercropping is illustrated by four excellent plates, but only once incidentally mentioned in the text; rotational and successional cropping are not mentioned at all. No help is given as to the selection of profitable varieties. The spade apparently finds no place even in the home garden, and many labour-saving devices, methods, and appliances well known here seem to be unknown there. Sub-irrigation is not mentioned, and only twenty-three crops are dealt with, whereas our market gardens accommodate nearly double that number (not including fruits and flowers). More notes upon the cost of raising crops, the returns to be expected, and the like, would have been valuable; only here and there is this mentioned.

F. J. C.

The Student's Handbook to the University and Colleges of Cambridge. Fourteenth edition. Revised to 30 June, 1915. Pp. 701. (Cambridge: At the University Press, 1915.) Price 3*s*. net.

THOUGH the statements made in the handbook are not official, every care has been taken by reference to competent authorities to make them accurate. The temporary emergency legislation occasioned by the war is recorded in this new edition. This legislation refers, among other matters, to the allowance of terms and examinations to students on active service, and the modification in their case of various fees; and also to the modification of certain examination regulations.

LETTERS TO THE EDITOR.

The Origin of New Adaptive Characters.

THE author of the article in NATURE of July 15 entitled "The Material Basis of Evolution" has misunderstood some of the chief bearings of my address entitled "Origin of Single Characters as Observed in Fossil and Living Animals,"[1] and I would regret to have certain passages in this well-intentioned review quoted as expressing my opinions. My address was based on researches carried on continuously since 1889 on the actual modes of origin of single specific and generic characters as observed in several lines of mammalian descent (horses, rhinoceroses, and titanotheres) in which such characters can be traced from their beginnings to their final development without any break. The term *numerical* was used as a convenient designation for all characters which may be expressed in numbers and formulæ, while the term *proportional* was used for such characters as may be expressed in indices and ratios.[2] There is a clear genetic distinction between these two kinds of characters, for while changes of proportion, such as the reduction of the lateral digits of the feet of horses, gradually lead into changes which may be expressed numerically, such reduction-changes fall under laws which govern quantitative changes in general rather than laws which govern the origin of new characters.

It is in the origins of new adaptive organs, such as the horn rudiments of the skull of mammals, that we observe another evolutionary principle in operation, whereby descendants of the same ancestors give rise to *similar* numerical characters, both in near and remote lines of descent, while at the same time they may give rise to entirely *dissimilar* proportional characters. In other words, there is some principle of ancestral hereditary predisposition or control in the origin of many new numerical characters which we cannot at present understand or explain. Nor can we now explain the causes of the origin of proportional characters, because both the Lamarckian and the Darwinian explanations fail in certain cases. The principle of ancestral predisposition also operates in the proportional evolution of nearly related lines of descent, although not in the remote lines.

The distinction between numerical and proportional is further sustained by the fact that modern mammalogists, such as Miller and Osgood, in their systematic treatises on carnivores and rodents, employ either proportional or numerical characters in all their definitions; in practically all systematic treatises on the hard part of mammals this distinction is used in definition. Proportional characters are far more common than numerical. The observations of Osgood, moreover, which are on an unprecedented scale, embracing the examination of more than 27,000 specimens of Peromyscus, are in absolute accord with my results obtained in palæontology, namely, that there is a complete continuity (rather than discontinuity or saltation) in the origin of proportional characters and in the origin of several, if not all, of the numerical characters observed.

As to the De Vries mutation hypothesis, it is ex-

[1] Presidential address before the Palæontological Society of America delivered in the Academy of Natural Sciences of Philadelphia, December 31 1914.

[2] Technically these terms are replaced by the designations "rectigradations" and "allometrons."

pressly not stated in my address, as quoted by my reviewer, "that there is no evidence whatever in support of the theory that 'species' may arise from fortuitous, saltatory characters." No such sweeping statement is made; on the contrary, the much more guarded statement is made (p. 229) that, "I do not know of a single instance where a field observer in mammalogy or in palæontology has recorded a new saltation [*i.e.* mutation] character which is known to be of any significance in the evolution of the race. . . . Saltation is, however, theoretically probable in certain numerical and meristic characters, such as supernumerary teeth and vertebræ."

Nor has the reviewer understood my observations regarding the nature of species and genera. The Darwinian tradition as to the actual modes of evolution of species, which is closely followed by De Vries and Bateson to-day, may be described as a "single character" or "group character" doctrine, namely, that the evolution of species manifests itself suddenly in one character or group of characters; that whenever such character or characters arise through individual variation or through saltation, they may be fixed in the race by selection. This was one of the essential features of our former conception of evolution, namely, that an organism advances now here, now there; it was drawn from ancient traditions about the nature of "species" entirely prior to the period of palæontological discovery of the actual modes of evolution of animal forms. These date back to the discovery of mutation by the German palæontologist Waagen in 1869, mutation in an entirely different sense from that of De Vries. Palæontology has now demonstrated that we must abandon this "single character" conception of evolution, because it proves that every organism is made up of an almost infinite number of characters, each of which is in a continuous state of movement, either originative, progressive, or retrogressive. This is a law well observed and established through palæontology, for which at present we offer no theoretical explanation whatever. The "single characters" and "group characters" of the older systematists and of Darwin are now seen to be those which, although part of a large general advance or retrogression, happen to be so conspicuous as to attract the eye of the zoologist. In my address this newly-discovered law of multiple-character evolution is shown to be entirely in accord with the theory of the "unit-character" constitution of the germ, which chiefly dates from Mendel's discoveries.

In regard to natural selection, I am not convinced, as my reviewer states, "that all characters must run the gauntlet of selection." On the other hand, I give it as my theoretic opinion (p. 239) that "Selection is operating always upon the sum of all the movements, actions, and reactions of characters known as the organism and upon all single characters [which happen to be] of survival or elimination value."

Finally, I cannot lend the least shadow of assent, as my reviewer states I do, to the recent enunciation by Prof. Bateson that we may have to forgo the theory of addition of germinal determiners and substitute a theory of evolution by loss of determiners. On the contrary, I expressly state that while palæontology offers the most positive testimony as to evolution by the loss of certain somatic characters, such as in the side digits of the horse (of which, by the way, most of the germinal determiners still persist), the law of incessant additions of new numerical and proportional characters such as transform the Eocene into the modern mammals certainly does not accord with Bateson's metaphysical conception that this outward progress and development may represent an inward loss of germinal determiners. The defect in Bateson's reasoning arises from the fact that in his special field of investigation the new laws and principles established in palæontology are not observable at all.

Of the three kinds of mammals mentioned above the group at present revealing the most complete and unbroken history is the titanothere family, which I have been engaged in monographing during the past fifteen years for the United States Geological Survey. The most significant result derived from the intensive study of the evolution of this family is the law of multiple-character evolution, namely, that evolution simultaneously progresses in every one of the innumerable single characters of which an organism is composed. Each character possesses its own individuality and separableness, each advances or lags behind according to its individual velocity, each subserves the general purpose of the entire organism through the uniting forces which we term correlation.

While writing, I would like also to correct an erroneous impression, for which my present reviewer is not at all responsible, as to my viewpoint regarding Lamarckism. In 1889 I held that the reaction-inheritance hypothesis of Lamarck was the only explanation we have for such directive or orthogenetic tendencies in evolution as are displayed especially in the origin of characters which I have termed "rectigradations." I subsequently—with Baldwin and Lloyd Morgan—discovered the organic-selection principle and abandoned the reaction-inheritance interpretation when I observed that while it may explain certain orthogenetic tendencies, it is directly contrary to others. Thus I am to-day in no sense a Lamarckian.

All that we can positively state at present is that the adaptive trend in the origin of new specific and generic characters is the resultant of the interactions of four sets of forces: germinal, environmental, ontogenetic, and selective, as expressed in the law of "tetraplasy." We know that these "actions," to quote Newton's phrase, are in continuous operation. We also know that in certain cases one or other of these four complexes of forces may be dominant, so that the visible changes which we observe in animals and plants may for a time be chiefly either ontogenic, or environmental, or germinal, or selective. But what may be the nature of the interactions between ontogenic, environmental, and selective forces on the germ-chromatin and the continuous origin of new adaptive characters in the germ-chromatin we have not as yet the most remote conception.

Finally, the chief purpose of my address was to show the real harmony which exists between the actual observations of palæontologists and of experimentalists and the distinctive principles which are most readily observed in these respective fields of research. HENRY FAIRFIELD OSBORN.

Columbia University, September 29.

PROF. OSBORN would have earned the gratitude of us all if he had produced some evidence in support of his assertion that "there is a clear genetic distinction between 'numerical' and 'proportional' characters." We still maintain that this connection cannot be demonstrated.

Neither can the reviewer admit that he has failed to understand Prof. Osborn's observations regarding the nature of species and genera. In the first place, Prof. Osborn's interpretation of the "Darwinian tradition," which he emphasises in this protest, is inadmissible, since it involves the assumption that the evolution of species manifests itself suddenly "in one character or group of characters." From his context he implies that according to this "tradition" a species, A, may give rise to species B, C, and D, each differ-

ing from the other in sharply-defined characters, which, being products of the germ-plasm, are transmissible, though they may be eliminated by selection. He contrasts this view, which is *not* according to the Darwinian tradition as commonly accepted, with his own—which is entirely "Darwinian"—based on osteological characters according to which the evolution of species is quite otherwise, demonstrating a condition of continuous development to be traced by means of, say, a horn or the cusp of a tooth; or, in other words, on "characters which happen to be so conspicuous as to attract the eye of the zoologist."

Having disposed of the Darwinian "tradition," he proceeds to point out a more excellent way of interpreting the mazes of evolution, and this by means of a "newly-discovered law of multiple-evolution" derived from the discoveries of palæontology, which "proves" that "every organism is made up of an almost infinite number of characters, each of which is in a continuous state of movement, either originative, progressive, or retrogressive." But this idea of "multiple-character evolution" cannot fairly be said to be new. Further, if Prof. Osborn has independently arrived at this conception of evolution, he has done so through his own wide knowledge of living animals, and not entirely, as he seems to believe, through his brilliant discoveries in palæontology. Palæontology, in short, cannot be said to "prove" that every organism is made up of an infinite number of characters . . ." for palæontology can "prove" no more than can be attested by such skeletal and dermal structures as are capable of fossilisation. The characters furnished by musculature, viscera, "behaviour," and the "emotions," for example, are all factors of evolution which can only be imperfectly inferred, not demonstrated, by the palæontologist.

In stating that Prof. Osborn could find "no evidence whatever in support of the theory that species may arise from fortuitous, saltatory characters," the reviewer felt that he was accurately interpreting Prof. Osborn's assurance that he did not "know of a single instance where the field observer in mammalogy or palæontology has recorded a new saltatorial character which is known to be of any significance to the race." Prof. Osborn's reference to teratological cases does not seem to help him.

The reviewer frankly admits that he was wrong in suggesting that Prof. Osborn was to be regarded as in sympathy with the theory of evolution by loss of characters.

THE REVIEWER.

Simple Device for Controlling the Movements of Paramœcia.

EVERYONE who is concerned in the teaching of elementary zoology knows the great difficulty of so controlling the movements of Paramœcium that students can distinguish the essential features of its structure. Of all the methods adopted for this purpose of which I have hitherto heard, none has ever given me such successful results as one which I tried recently in this department as an experiment, and the advantages of which combine simplicity with very great control over the animals.

A small quantity of ordinary gum is painted on a glass slide, and allowed to become nearly dry; a drop of water containing the Paramœcia is then placed on the gum and covered in the ordinary way with a cover-glass. At first the gum will scarcely interfere with the movements of the animals at all, but within a few minutes, as the gum diffuses through the water, they will be seen to move more and more slowly, and ultimately they will be unable to move at all. Finally, the irritation caused by the gum will result in the discharge of the trichocysts.

This method of using the gum enables the student to observe the Paramœcia at first in an almost normal condition, and afterwards to make a careful and detailed examination of them at his leisure. The normal shape and appearance are retained for a long time, even when the animal has become stationary, save that the gullet tends gradually to disappear, possibly through clogging with the gum.

MONUMENTS AND LIGHTNING.

THE liability of monuments to be struck by lightning is the subject of a recent memoir in the *Atti della Pontificia Accademia dei Nuovi Lincei* by Prof. Ignazio Galli. The occasion of this note was the destruction at Santamaria di Capua Vetere, in the province of Caserta, in October, 1914, of a fine monument erected in 1895 in memory of the battle fought near to Volturno in 1860. This monument of travertine marble, about 95 feet high, consisted of a stately column on a substantial pedestal, surmounted by a colossal bronze statue of Victory about 10 feet high, weighing 1500 pounds. This statue was fixed in the summit of the column by an iron rod which penetrated about half-way down the column. The monument stood in the quadrangle of the communal building, far from any high trees. During a violent thunderstorm about 2 a.m. a lightning stroke threw down the great bronze statue, and destroyed the upper half of the column. It is thought that the destruction might have been averted had an efficient metallic conductor connected the bottom of the iron rod to a damp stratum of soil. It is evident that an insulating mass of marble, many feet high, between a metal object and the earth affords no protection whatever against a severe thunder-stroke.

Prof. Galli takes occasion to refer to similar catastrophes which befell a column at Constantinople in the year 548, and another dedicated to Constantine the Great in the same city in the year 1101. In Rome in the fourteenth century the column of Marcus Aurelius Antoninus was badly damaged at the top; and in the same century the statue of Trajan on the summit of the celebrated column of Trajan was likewise destroyed. Tacitus records how in the year 61 A.D. the Baths of Nero, erected scarcely one year before, were destroyed by lightning. More recent times have witnessed the destruction of the tower of the Castello of Milan (1521), that of Ivrea (1676), of San Nazaro at Brescia (1769), and of the fortress of the Lido at Venice (1808). In 1572 the flagstaff of the Castle of St. Angelo in Rome was destroyed, with the bronze statue of the Archangel Michael. Between the years 1606 and 1809 the basilica of St. Peter's was struck, generally on the cross or the golden ball, at least twenty-two times. On the last occasion (1809) the Pope, Pius VII., had already begun preparations for fixing lightning conductors. For more than a whole century these conductors have effectually preserved the structure from damage.

PERSIA.[1]

COL. SYKES has long won a position of authority and distinction in Persian questions by his travels and studies, including the well-known "Ten Thousand Miles in Persia," an "ouvrage couronné" (by the Royal Geographical Society) more than ten years ago. But for many years he has cherished the idea of a Persian history, only now fulfilled—the crown of his labours. Sir John Malcolm's "History of Persia from the most Early Period to the Present Time" appeared in 1815, and since that time no English Orientalist has attempted the same task on a similar, or adequate, scale. Sir Clements Markham's useful "Sketch of the History of Persia" (1874) does not claim to come into the comparison—excellent as it is. Since Malcolm's work, a century ago, the field of investigation has been transformed; mines of buried treasure have shown something more than "neglected agricultural land." The cuneiform inscriptions have been deciphered; such records as the cylinder of Cyrus and the Behistun record of Darius have been discovered and interpreted; historic sites have been excavated; we have in a measure evoked the spirit of ancient Persia. The modern world is now in a position to understand to some degree the Persian side in the struggle with Hellas and with Rome, and to revise old notions, based exclusively upon Western information and Western views. Ancient Persia can no longer be treated as a mere barbaric despotism, which has contributed nothing to civilisation.

Col. Sykes has special advantages from his close personal knowledge of so much of the ground; for twenty-one years he has lived in Persia; as a diplomatist, a soldier, a traveller, and a student he has seen the Middle East from various sides and penetrated many disguises. Peculiarly good, among many good things, are the geographical and topographical sections and references, such as the chapters that introduce the work ("Configuration, Climate," etc.), and the constant elucidations of history through the personal wanderings and investigations of the writer. Archæology and topography are well combined in the account of the great ruined sites of Achæmenian and Sasanid Persia, and the history of culture is not forgotten in the sections given to Persian customs, language, letters, and art, in various periods.

This book seems to give a fresh interest and value to the time of early Persian greatness—from the rise of Cyrus to the death of Darius Hystaspes—as well as to that attractive and neglected subject of the Sasanid kingdom, where "Asiatic slaves" appear struggling so long and so successfully against the Far Eastern expansion of Rome. The whole subject of Zoroaster and fire worship is sympathetically treated, and one may learn much of Old Persian architecture, art, and poetry from these pages.

In the Abbasid period of Muhammadan rule the author well develops the subject of Persian influence—so notably revived, after a time of deep depression, by the overthrow of the Umayyads and the transference of the capital from Syrian Damascus to Baghdad on the Tigris. The reader may be referred to the forty-ninth, fiftieth, and fifty-fourth chapters: "Persian Ascendancy in the Early Abbasid Period," "The Golden Age of Islam," and "Persian Literature before the Mongol Invasion," some of the most interesting and valuable in this work.

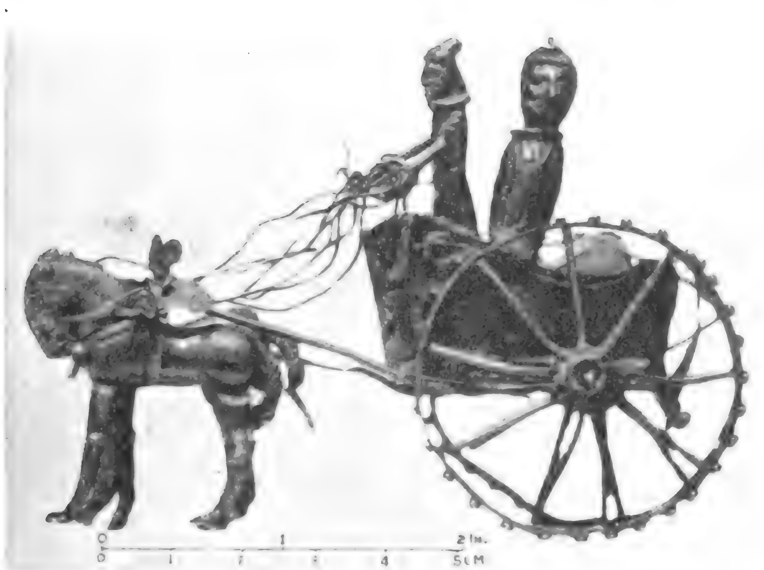

FIG. 1.—Gold model of Achæmenian chariot. (From "Treasure of the Oxus.") From "A History of Persia."

The Mongol Ilkhanate of Persia, in its political history, might perhaps have been made more of (except for the reign of the ugly and glorious dwarf, Ghazan, which is fully appreciated); on the other hand, the survey of Persian literature and art under the Mongols is very useful. But no part of this history is more serviceable, for none fills a more evident want, than the picture of the rise and fortunes of the new independent Shiite Persia, after the fall of the Timurids, in the sixteenth century. Of few parts of Persian story is it perhaps more difficult to gain really good information and criticism; of few parts is there more general ignorance.

The illustrations, by themselves, are noteworthy, and place us under a debt to the author, who has furnished many from his own collections and photographs. Some excellent things come

1 "A History of Persia." By Lieut.-Col. P. M. Sykes. Vol. i., pp. xxvi +544. Vol. ii., pp. xxii+565. (London: Macmillan and Co., Ltd., 1915.) Price 50s. net, two volumes.

from Hommaire de Hell's "Voyage en Turquie et en Perse," Layard's "Nineveh," J. de Morgan's "Délégation en Perse," Dieulafoy's "L'Acropole de Suse" and "L'Art antique de la Perse," the "Treasure of the Oxus," and Martin's "Miniature Painting in Persia"; Vereshchagin's pictures of Russian Central Asia have also been laid under contribution; and the author's industry and enthusiasm have collected treasures from many other sources. Besides the headpieces of the chapters, reproducing early coins, seals, gems, medallions, vases, cylinders, inscriptions, armour, and scenes of war, chase, and agriculture, more than 160 full-page designs, some in colour, are true illustrations of an admirable work. The seven maps are perhaps somewhat less pleasing and effective, though mostly of good average merit; that of Central Asia, facing p. 84, vol. ii., leaves one cold; that showing the Persian provinces, under the Abbasids, vol. ii., p. 62, is perhaps the best. Some of the pictures (among which, of course, none are "fancy") are of striking beauty, interest, or clearness: one might instance the "Ararat" of vol. i., p. 4, the "Friezes of the Archers," and "Lions" at Susa, facing pp. 58 and 194 in the same volume; the photographs of Bandar Abbas, Yazd, and Kirman, by H. R. Sykes, in vol. ii.; the specimen chariot of the First Persian Empire (i., 150), the tomb of Cyrus (i., 164), the captivity of Valerian in the hands of Shapur (i., 432), the tomb of Timur (ii., 214), and several of the author's own photographs (*e.g.*, ii., 340, 342).

It is perhaps open to criticism that so much space has been given to early Oriental matters before Cyrus, and that such deep digressions are sometimes made into external history of later time, well away from the main subject (see chaps. 4–7, 20, 44–6). The comparative value of the great figures of the Persian stage may be sometimes overrated; even Alexander of Macedon is perhaps a case of this. One could wish that Col. Sykes had given the Behistun inscription in full. In his picture of Zoroastrianism he scarcely seems to allow sufficiently for shadow as well as light, for readiness to persecute as well as for "good thoughts, good words, good deeds" (*Humata, Hukhta, Hvarshta*). It was not merely from the Church of Rome, but from the Catholic Communion in East and West that the Nestorians broke off. But the whole book is delightful, and one cannot but hope that it will be widely read and carefully studied; it is sure to be enjoyed.

FIG. 2.—Kupkan, the home of Imam Kuli. From "A History of Persia."

THE SAN FRANCISCO MEETING OF THE AMERICAN ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE.

SINCE the American Association, in 1902, definitely changed the date of its regular meetings to mid-winter it has, prior to the present year, held two summer meetings—one in Ithaca,

at Cornell University, in June, 1906, and one in Hanover, at Dartmouth College, in June, 1908. During the past summer advantage was taken of the World's Fair at San Francisco and the celebration of the completion of the Panama Canal to hold the first Pacific Coast meeting at San Francisco, Stanford University and the University of California, under the presidency of Dr. W. W. Campbell, director of the Lick Observatory of the University of California, at Mount Hamilton.

The meeting opened on Monday, August 2, with addresses of welcome by Mr. W. H. Crocker, first vice-president of the International Exposition, Dr. B. I. Wheeler, president of the University of California, and Dr. D. S. Jordan, chancellor of the Leland Stanford Junior University. Prof. H. F. Osborn, of the American Museum of Natural History, responded on behalf of the Association, and Dr. Campbell delivered an address entitled "Science and Civilisation."

The sessions of the different sections of the association and of the affiliated societies were held on Tuesday, Thursday, Friday, and Saturday of the same week in the buildings of the University of California, at Berkeley (across San Francisco Bay), and the sessions of Wednesday were held at Leland Stanford Junior University, at Palo Alto, an hour away from San Francisco by rail. On Monday evening a general reception to visiting members was held in the California Building on the Exposition grounds at San Francisco. On Tuesday, Thursday, and Friday public addresses were given as follows: Tuesday, by Prof. R. A. Daly, of Harvard University, on problems of the Pacific Islands; Thursday, by Prof. W. B. Scott, of Princeton University, on the isthmus of Panama and its influence on the animal life of North and South America; Friday, by Prof. P. S. Reinsch, American Ambassador to China, on the economic future of the Pacific.

The following affiliated societies held meetings: American Mathematical Society, Astronomical and Astrophysical Society of America, American Physical Society, Geological Society of America, Paleontological Society of America, Seismological Society of America, American Society of Naturalists, American Society of Zoologists, Entomological Society of America, American Association of Economic Entomologists, American Phytopathological Society, American Fern Society, American Psychological Association, American Anthropological Association, Archæological Institute of America, and the American Genetic Association.

Many excursions to points of scientific interest on the Pacific Coast were given. About six hundred members were in attendance. All the arrangements for the meetings were in the hands of the newly-organised Pacific Coast division of the American Association, which prepared a source book of information upon the natural aspects of the Pacific Coast and upon the developments which have given to the Pacific Coast its peculiar interest. It has been published under the title of "Nature and Science on the Pacific Coast."

Several interesting and rather important symposia were held, notably one on the physics of the air, under the auspices of Section B and the American Physical Society; three on the correlation of the Triassic, the Cretaceous, and the Miocene, under the auspices of the Paleontological Society of America; and one by the American Society of Zoologists on the *rôle* of variation and heredity in evolution. An important series of papers was presented by the Botanical Society of America on the geographic distribution of plants. A symposium was also held by the Educational Section of the Association and the American Association for the Study of the Feeble-Minded on the subject of mental tests and their pedagogical significance. The American Anthropological Association brought together a series of papers on the history of civilisation in the Pacific area and another on the social aspects of race factors in the Pacific area.

SIR ARTHUR RÜCKER, F.R.S.

ON Thursday last, in the afternoon of a still November day, amidst the russet and gold of the dying year, all that was mortal of a high-minded, courteous, cultured man—the true type of an English gentleman—Sir Arthur Rücker, a very "gentle knight" indeed, was committed to earth in the graveyard of the Berkshire village church in which for some years back, and so long as his waning strength permitted, he was accustomed to worship. His end came peacefully, for he died in sleep, apparently without pain, and so quietly that it was hard to realise that his beautiful spirit had indeed passed away. He had borne with characteristic courage, patiently and uncomplainingly, an illness which he well knew to be mortal. Although one of the most modest of men, he must have realised that he had made of his life a great success, for almost every mark of appreciation and esteem that can fall to the lot of a man of science had been accorded to him. It was but natural, therefore, that when freed from the cares and responsibilities of a high position, and with an ample competency, he should have looked forward to years of a dignified leisure in which to resume his studies and to follow the pursuits of the country life he loved so well. But it was not to be. He had barely taken off his harness when signs of the fatal malady made themselves manifest. Yet no embittered word or complaint ever escaped him, and he met the inevitable end with the calmness, resignation, and fortitude of a martyr.

Born in 1848, at the time of his death he had just completed his sixty-seventh year. He was the eldest son of Mr. D. H. Rücker, a City merchant living at Errington, Clapham Park. I was privileged to see a little of the home-life at Errington, and I recall the head of the house as a polished, courtly gentleman with a benign manner, reminiscent of Addison's worthy knight, and I well remember, too, the pleasing deference and affectionate respect with which father and son regarded and addressed each other. The family

was of Hamburg origin, but had been settled in this country for generations. Another branch had given a professor to the University of Leyden, and his portrait is to be seen in the senate house.

Arthur William Rücker received his early education at the Clapham Grammar School, at one time under the direction of the Rev. Charles Pritchard, F.R.S., who subsequently became Savilian Professor of Astronomy at Oxford. Here Rücker gained that grounding in mathematics to which much of his success as a teacher and investigator was due. From Clapham he proceeded to Oxford, and was entered at Brasenose. After a brilliant career as an undergraduate, with special distinction in mathematics, he was elected a fellow and lecturer of his college, and became demonstrator of physics in the Clarendon Laboratory. Oxford made a deep and lasting impression upon Rücker, apart from her effect upon his career as a man of science, for he came there under influences which profoundly affected his religious convictions and shaped the whole course of his spiritual life. He seldom cared to speak of sacred matters even to his most intimate friends, but to those who were admitted to his confidence it was evident how much he realised he owed to his Alma Mater in this respect and with what grateful affection he regarded her.

My acquaintance with Rücker dated from 1874. In that year we, together with the late Professor Green, who afterwards occupied the chair of geology at Oxford, were elected as the first teachers in the newly-created Yorkshire College, Leeds—Rücker as professor of mathematics and physics. Its habitation at that time was in the disused Bankruptcy Court, a somewhat woebegone, ill-constructed building which, after a checkered career, had been turned into a school of cookery. Unfortunately the gastronomic experiments of the pupils had succeeded in setting fire to the place, and my first meeting with Rücker was over the charred beams of the principal room. The spectacle that this prospective seat of science and learning then presented seemed sorrowful enough, but, nevertheless, to the budding professors it had in it a certain element of humour. As we could not hear of any students, the circumstance that there was no proper place in which to teach them was not, perhaps, of pressing importance. But Yorkshire grit and energy soon got the place into something like shape. The old court-room was eventually converted into a fairly good lecture theatre; there was laboratory accommodation for about a couple of dozen workers, two or three small classrooms, with some provision of what were euphemistically termed professors' private rooms. At length we were able to make a belated start with as many students as could be counted upon the fingers of one hand. Such was the beginning of the institution which has developed into the University of Leeds, with an eminent professoriate in numerous faculties, housed in handsome buildings, with well-equipped laboratories, workshops, and classrooms, spacious libraries and museums, a long roll of graduates in arts and science, and an annual entry of many hundreds of students of both sexes. Towards this consummation Rücker worked unremittingly. From the outset he threw himself heartily into the intellectual life of Leeds, was an active member of its Literary and Philosophical Society, and became associated with certain of the educational organisations in the district. His energy, capacity, soundness of judgment, and business aptitude were soon appreciated by his colleagues, and quickly gained for him the complete confidence of the governing body. Moreover, he developed into an excellent teacher. He was an admirable lecturer, with a remarkable power of exposition and a gift of felicitous phrase, which, with a certain delicate, restrained sense of humour, made him delightful to listen to.

Rücker never took any very strong interest in mere party politics, but as a young man his political sympathies were distinctly Liberal. Nothing, perhaps, more strikingly illustrates the influence and position he acquired in the town than the fact that in the election of 1885 the party managers should have invited him to contest North Leeds, a Conservative stronghold, and then reckoned a safe seat for Mr. Lawies Jackson, now Lord Allerton. It was one of the most strenuous contests ever fought in that division, Rücker being beaten by only 257 votes on a poll of nearly 9000. In the following year came the great Disruption, and Rücker as a Liberal Unionist unsuccessfully fought the Pudsey division.

Somewhat to the surprise of his colleagues, and greatly to their regret, he now severed his connection with the college. Thanks in a large measure to his untiring efforts, his constructive ability and skill in negotiation, he had seen the institution raised to the rank of a constituent college of the Victoria University, and thanks also largely to his influence with the governing body, it was now in a habitation worthy of its position. With no immediate prospect of entering public or political life, he returned to London and again took up his residence with his parents at Clapham.

In the following year I followed him as successor to the late Sir Edward Frankland in the Normal School of Science, South Kensington. On the death of Prof. Guthrie in 1886, I succeeded in inducing Rücker to reconsider his decision to abandon the career of a teacher, and with the cordial concurrence of Huxley, then dean of the School, and of the authorities of the Science and Art Department, he was invited to occupy the vacant chair of physics, and he resumed what really was his true vocation with all the energy, ability, and success that had attended his work in Leeds. At South Kensington, as at Leeds, it became our duty, by direction of the authorities, to prepare plans for a considerable extension of the laboratories and classrooms of the Royal College of Science, and to Rücker's thoughtful prevision, experience and mastery of detail, combined with the planning of Sir Aston Webb, the present admirable physical laboratories of the

Imperial College of Science and Technology are due.

In 1901 Rücker was induced to accept the principalship of the reorganised University of London. He had been a member of the old senate since 1890, and had acquired an intimate knowledge of the working of the University, its aims, and somewhat divergent policy. In undertaking the principalship he undoubtedly entered upon the most difficult and most arduous position he was ever called upon to fill. To a man of less courage, tact, and patience his situation would at times have been intolerable. He had very definite views, based upon knowledge and a ripe experience of the true functions of a great metropolitan University, and had on several occasions, both in speech and in writing, given public utterance to them. But as a man of affairs, accustomed to the conflict of discordant aims and the clash of vested interests, no one knew better how often in this imperfect world the better is the enemy of the good. No one was more ready to appreciate the strength of an opponent's position or to realise the value of compromise, and his sympathy, his sense of fairness, his unfailing courtesy, and his skill in diplomacy constantly enabled him to get the best out of a compromise. To his intimate friends he had communicated his intention of resigning his position when he should have reached his three-score years. During the seven years he held it he had the satisfaction of bringing about the incorporation, as constituent parts of the University, of the two leading London colleges, with the consequent strengthening of the internal side. He gave up his office to the great regret of all who served with or under him, and with a unanimity in expression of good-will, esteem, and friendship from all sections which greatly touched him at the time, and of which he had a grateful recollection.

Rücker was elected into the Royal Society in 1884, was a member of council in 1887–89, and again in 1894, when he became one of the secretaries. No man ever filled that office with greater acceptance. During the five years he held it he brought to the exercise of its duties the same habits of industry and the same mental and personal characteristics that had marked his discharge of every position he had undertaken.

In 1891 he became treasurer of the British Association, in 1898 a trustee, and in 1901 president. He took an active share in the formation of the Physical Society, served on its council, and was its president in 1893–95.

Rücker, as might be supposed, was frequently called upon to serve upon Royal Commissions and Departmental Committees, and much of his time and energy was spent in such public service. He was a member of the Royal Commission on Irish Universities in 1906; on the University of Belfast Commission in 1908, in which year he was also placed on the Carnegie Trust for the Scottish Universities. He was a member of the Board of Trade Committee on Sight Tests in 1910, and of the Royal Commission of the 1851 Exhibition in 1911. He acted as deputy chairman of Lord Rayleigh's Committee which led to the foundation of the National Physical Laboratory; he served on its governing body, and, so long as the state of his health permitted, took an active interest in its development.

Rücker's list of scientific papers is comparatively short, and it cannot be said that he has left any marked impression upon British physics. There can be no question, however, that he possessed all the essential attributes of a successful investigator. But, as it happened, circumstances, not always of his choosing, placed him in positions in which his time, energy, and mental powers were practically wholly absorbed by matters unconnected, or at most only indirectly connected, with physical inquiry. At the same time he was keenly interested in the progress of science, and was an omnivorous reader of contemporary scientific literature. It was easy to engage his attention and to excite his interest in any problem which he thought his knowledge or mathematical ability might possibly elucidate. Some of his early papers were joint productions on subjects of physical chemistry contributed by us to the Journal of the Chemical Society. On one occasion he was induced to address the society on the Range of Molecular Forces (published in the Transactions for 1888), in which he incidentally gave an account of the joint work of Prof. Reinold and himself on "The Properties of Liquid-films" (Phil. Trans., 1881 and 1886).

But Rücker's chief contribution to science was his share—and it was by far the more important share—in the Magnetic Survey of the British Isles for the epochs 1886 and 1891, the results of which were published in their final form in 1896 as a separate volume (vol. clxxxviii) of the Philosophical Transactions. Space precludes any attempt to tell the story of how the Survey originated and how Rücker was induced to take an active interest in Terrestrial Magnetism. He showed himself an excellent observer, and became very expert in the use of the Kew pattern of magnetometer in the field, where, in a variable climate like ours, it is frequently necessary to be prompt as well as accurate. He organised the whole of the tedious work of reduction, checking, and tabulation, and upon him fell the chief burden of putting together the outcome of our discussions of the results. The first memoir was made the Bakerian Lecture for 1889, and the Society indicated its high appreciation of Rücker's work by recommending him for a Royal Medal in 1891. It is but just to him to say that the memoir in which he embodied the results of our joint labours, extending over some fourteen years, marks a new departure in work of this kind, and that its influence is plainly evident in similar surveys which have been subsequently carried out in various parts of the world.

Rücker was married twice. His first wife was Marian, daughter of Dr. J. D. Heaton, F.R.C.P., the first chairman of council of the Yorkshire College. She died in 1878, leaving a daughter, now Mrs. Reginald Hooker. His second wife, whom he married in 1892, is Thereza, daughter

of the late Prof. Story-Maskelyne, F.R.S., of Basset Down, Swindon. They have one son, Nevil, who, after doing duty in the Secretary's Department of the War Office shortly after the outbreak of the war, is now on active service.

T. E. THORPE.

NOTES.

WE regret to learn that Dr. Theodor Boveri, professor of zoology and comparative anatomy in the University of Würzburg, died there, after a long illness, on October 15, at fifty-three years of age.

THE death occurred on November 5, at sixty-three years of age, of Mr. J. Sinclair, editor of the *Live Stock Journal* and the *Agricultural Gazette*, and author and editor of many standard works on stock-breeding and agriculture.

WE learn from *Science* that Prof. Augustus J. Du Bois, for thirty years professor of civil engineering in the Sheffield Scientific School, Yale University, died on October 19, at the age of sixty-six years; and that the Rev. C. M. Charroppin, S.J., formerly head of the department of science of St. Louis University, died on October 17.

THE following have been elected officers of the Cambridge Philosophical Society for the ensuing session, 1915–16:—*President*: Prof. Newall. *Vice-Presidents*: Dr. Shipley, Dr. Fenton, Prof. Eddington. *Treasurer*: Prof. Hobson. *Secretaries*: Mr. A. Wood, Dr. Arber, Mr. G. H. Hardy. *New Members of the Council*: Dr. Bromwich, Dr. Doncaster, Mr. C. G. Lamb, Dr. Marr, Mr. J. E. Purvis.

AT the annual meeting of the Faraday Society on October 19 the following officers and members of council were elected to serve for the year 1915–16:—*President*: Sir Robert Hadfield. *Vice-Presidents*: Prof. K. Birkeland, Bertram Blount, W. R. Bousfield, K.C., Prof. F. G. Donnan, Dr. Eugene Haanel, Prof. A. K. Huntington, Dr. T. M. Lowry. *Treasurer*: Dr. F. Mollwo Perkin. *Council*: W. R. Cooper, Dr. C. H. Desch, Dr. J. A. Harker, Emil Hatschek, Cosmo Johns, Prof. A. W. Porter, E. H. Rayner, A. Gordon Salamon, Dr. G. Senter, Cav. Magg. E. Stassano.

A FURTHER appeal is made for the presentation or loan of telescopes for use with the batteries at the Front. Large telescopes on stands, deer-stalking telescopes, good pocket telescopes—in short, any type except toys are acceptable. Astronomical eye-pieces, etc., not wanted on service, are removed before issuing and marked with a number identical with that engraved on the telescope. Offers or instruments should be sent to the secretary, Lady Roberts's Field Glass Fund, National Service League, 72 Victoria Street, S.W.

IT has been found necessary to make certain alterations in the arrangements originally made for the London meetings of the Institution of Electrical Engineers. The revised programme for the immediate future is:—November 18, the inaugural address of the president, Mr. C. P. Sparks; November 25, "Some Difficulties of Design of High-speed Generators," by Prof. A. B. Field; December 16, "The Design of High-pressure Distributing Systems," by J. R. Beard; January 13, "The Predetermination of the Performance of Dynamo-Electric Machinery," by Prof. Miles Walker; January 20, "The Possibilities in the Design of Continuous-current Traction Motors," by N. W. Storer.

THE President of the Board of Agriculture and Fisheries has appointed a Departmental Committee to make arrangements with a view to the maintenance, so far as possible, of adequate supplies of fertilisers for the use of farmers in the United Kingdom. The Committee is constituted as follows:—The Right Hon. F. D. Acland, Parliamentary Secretary to the Board of Agriculture and Fisheries (chairman); Mr. R. H. Rew, Board of Agriculture and Fisheries; Mr. T. H. Middleton, Board of Agriculture and Fisheries; Mr. G. J. Stanley, Board of Trade; Mr. J. Dundas White, Scottish Office; Mr. H. Ross Skinner, Ministry of Munitions; Mr. E. J. Foley, Admiralty; Mr. R. J. Thompson, Board of Agriculture and Fisheries. The secretary of the Committee is Mr. H. D. Vigor, 3 St. James's Square, London, S.W.

THE death is announced of Dr. Gaston Vasseur, professor of geology in the University of Marseilles, at the age of sixty years. His early works on the Tertiary formations of the Paris basin and the west of France placed him in the first rank of French stratigraphical geologists, and for many years he was employed by the Geological Survey of France in preparing the detailed map of the south-western area, which he had the satisfaction of completing. He also published as an independent work an important geological map of the whole of France. During the progress of his researches in the field he amassed a great collection of fossils, now in the museum of Marseilles, where it still awaits detailed study and description.

THE death is announced of Dr. C. J. Bouchard, professor of pathology in the University of Paris. Born in 1837, Prof. Bouchard received the early part of his medical education at the Lyons Medical School before entering the faculty of medicine of the University of Paris, where he graduated in 1866. He was appointed professor of pathology in the University of Paris in 1873, afterwards acting as dean of the faculty of medicine. In 1887 he became a member of the Institut, and later an officer of the Legion of Honour and president of the Academy of Sciences. He laboured devotedly for more than fifty years at clinical medicine and general pathology, conducting research work which in many directions materially influenced the course of practical therapeutics. He worked upon ptomaine poisoning and autointoxication, on the functions of the leucocytes, on the pathology of nutrition, on the bactericidal power of the blood, immunisation and vaccination, on radiology, and on many of the problems of tuberculosis. He published several works, including a justly popular text-book of pathology. He took a considerable part in bringing about friendly relations between French and British doctors, and was chairman of the committee which organised the visit of British

medical men to Paris in 1905. Prof. Bouchard was held in high regard in France and abroad, and his death will be generally regretted.

By the death of Lieut. Gordon Sanderson, killed in France on October 13, the Archæological Survey of India has lost the services of a young officer of great promise. Mr. Sanderson was born in 1886, and, after serving for a time in the Egyptian Public Works Department, was appointed in 1910 an assistant superintendent in the eastern circle of the Archæological Survey of India. At the end of 1911 he was transferred to the northern circle as officiating superintendent of Muhammadan and British Monuments, while Dr. Ph. Vogel was acting general superintendent in the absence of Mr. Marshall. His appointment was confirmed in March, 1912. At the beginning of the present year he received permission to transfer to the military department, and was attached to the 2nd Batt. 2nd Gurkhas. Mr. Sanderson's work in the northern circle was especially concerned with the conservation of the important examples of Mughal art in Delhi, Agra, and Lahore. Some few years ago, arrangements were made whereby the royal palaces, which had been used as barracks, were evacuated by the military authorities and handed over to the survey. Mr. Sanderson ably continued the work of restoration made possible by the transfer. Its progress was announced from time to time in his contributions to the annual reports of the survey. These included a description of the Shāh Burj, a pavilion built by Shah Jehan, and restored by the late Mr. Froude Tucker in 1908, a report on conservation in Agra and the neighbourhood, and an account of Shāh Jehan's Fort at Delhi, in which his powers of lucid description were ably seconded by his skill as a draughtsman.

With much regret we announce the death of Mr. Donald Ewen, who was killed while tending the wounded between the lines near Loos about a fortnight ago. Mr. Ewen was serving at the time as a private in the London Scottish Regiment, but an order for his recall, to take up important work at the National Physical Laboratory, had been issued by the War Office; he is thus another of those sad cases where a promising young man of science, who was to have returned home for important work, has been killed just before the order was to be carried out. Mr. Ewen was born in Birmingham in 1887, and educated at Oundle School and Birmingham University, taking his M.Sc. in metallurgy in 1910, and gaining the Wiggin and Bowen research scholarships. He then entered the National Physical Laboratory, where he was to attain the grade of assistant on his return from France. He published many papers on metallurgical subjects, collaborating with Prof. T. Turner, of Birmingham, and, more recently, with Dr. W. Rosenhain, of the National Physical Laboratory. The latter papers dealt principally with the hypothesis of the existence in metals of an amorphous intercrystalline cement, and Mr. Ewen's careful experimental work did much to establish the theory as a well-based working hypothesis. His death is to be regretted, not only as that of a cheerful and enthusiastic personality, but also as a research worker in a field that urgently needs cultivation, and one from whom further important contributions to metallurgical science might well have been expected.

Capt. W. Loring, of the 2nd Scottish Horse, who died on a hospital ship on October 24, from wounds received at the Dardanelles, had in earlier years done distinguished work in classical archæology. After a brilliant career at Eton and Cambridge, he went out in 1889 as a student of the British School at Athens, and for the three following years remained at the school as Craven student. During that period he took an active part in excavations, notably in those at Megalopolis, besides undertaking on his own account a complete topographical survey of Arcadia. When he settled in London, as an examiner in the Board of Education, he held for a time the post of secretary to the school at Athens, and it was during this period that he volunteered for service in South Africa, first as a trooper in a yeomanry regiment, and then with a commission in the Scottish Horse. He was severely wounded, was twice mentioned in despatches, and received the Distinguished Conduct Medal. He left the service of the Board, where he had been private secretary to Sir John Gorst and Sir William Anson, in order to become director of education under the Education Committee for the West Riding of Yorkshire, but vacated the post through a difference of opinion with his committee, and about a year later, in 1905, became warden of the Goldsmiths' College, New Cross, a post he held until his death. He had always kept in touch with the Scottish Horse, and when the present war broke out he at once rejoined the colours, and after a year's training in England went out to the Dardanelles with the regiment in August last. In Capt. Loring the country has lost a man of real ability, of remarkable force of character, and single-hearted devotion to duty.

With the passing away of Prof. James McCall, principal of the Glasgow Veterinary College, on November 1, at the advanced age of eighty-one years, veterinary science has lost one of its greatest and most highly esteemed exponents. Educated at Wallacetown and Ayr Academies, he was intended for the legal profession, but that work did not prove congenial. Consequently he soon deserted it, and enrolled as a student at the Dick Veterinary College, Edinburgh, where he qualified as a member of the Royal College of Veterinary Surgeons in 1860, and afterwards obtained his fellowship in 1877. His enthusiasm for the progress of veterinary science enabled him to overcome opposition on the part of existing veterinary colleges when he applied for a charter for the establishment of the Veterinary College of Glasgow in 1862. The charter was, however, granted and signed by the late Queen Victoria in 1863. From that time the college has steadily progressed, and has been transformed from a private to a public incorporated institution, approved and supported by the Scotch Education Department, the powers of which have now been transferred to the Board of Agriculture for Scotland. The alumni of the institution include some of the most notable exponents of veterinary science, both in the British Isles and the Colonies,

and they are at one in attributing their success to the excellent teaching and example of the late principal. Prof. McCall was a man of action, and did not resort much to the pen. His outstanding abilities were early recognised by the Government and local authorities. He might be described as one of the pioneers of veterinary public health, recognising as he did the importance of veterinary inspection of meat and of dairies, and it was largely owing to him that Glasgow earned the distinction of being the first city to introduce the safeguard to public health on those lines. Amongst his professional honours, Prof. McCall was president of the Royal College of Veterinary Surgeons 1890–91, vice-president 1868–9, 1871, and 1873 to 1879, and member of the council 1884–95, and 1899–1915.

DR. SIDNEY COUPLAND'S Harveian oration, published in the *Lancet* of October 30, deserves careful study. Not that we need admire the existence of Harveian and Hunterian orations. It is absurd, thus to make immortality compulsory. There have been a hundred orations in memory of Hunter, and many more than a hundred in memory of Harvey. The result is, that the more courageous orators are venturing to hang their own special subjects on these two exalted pegs: so that we have a Hunterian oration on some new discovery which "would have interested Hunter," or on some new method of treament "not dreamed of in the days of Harvey." These monumental antiquated lectures ought to be on a different man each time—Vesalius, Paré, Jenner, Cooper, Darwin, Pasteur, Lister: a whole host of immortals are waiting their turn. But Harvey's life is always worth hearing of; he might be added to Hazlitt's list of people whom one would like to meet. He lived in wonderful times, and he was a man of great charm and distinction of character, apart from his mighty work in physiology. On Harvey's scientific work Dr. Coupland hangs his own authoritative subject, the pathology and the treatment of insanity. Nothing in all medicine and surgery is more worthy of note than the present materialistic study of "mental diseases." It is bound to give results of very great and lasting value; it is miles ahead of the old psychological talk, which was a sort of Linnean classifying; it has revolutionised our concepts of insanity, and it will provide new resources for the treatment of the insane. But if the men of science and the physicians are to do their best, they must have the help of public opinion. The old half-superstitious, half-sentimental terror and hatred of insanity must be put away—easier said than done, but worth doing—and we must all be prepared to support any good national plan which can be devised for the early detection, isolation, and treatment of incipient cases.

A NEW part of the Proceedings of the Prehistoric Society of East Anglia begins the second volume of the publications of this active society. Like the previous parts, it is well illustrated by plates and text-figures, chiefly of implements, and it deals with many subjects of more than local interest. In his presidential address Mr. J. Reid Moir returns to the question of flint implements found beneath the Red Crag of Suffolk; and in a subsequent paper he discusses a series of mineralised fragments of bone from below the base of the Red and Coralline Crags, which he considers to be implements of a primitive type made by man. A valuable account of the sub-Crag detritus bed itself is contributed by Mr. Alfred Bell. Mr. R. H. Chandler describes implements of the Les Eyzies type from a working floor in the Cray valley, Kent, and Mr. Henry Dewey discusses the surface changes since the Palæolithic period in Kent and Surrey. According to Mr. Dewey, "there can be no doubt that flint implements characteristic of widely different periods all occur together on the surface of the Kent and Surrey hills. The mere fact of their occurrence in considerable numbers suggests continuous occupation of the sites from early Palæolithic to late Neolithic times; and that no destructive agencies of sufficient power to remove them acted either during or since the time of their deposit."

REFERENCE has been made in these columns to the Economic Bulletins on "The House-fly as a Danger to Health" (No. 1), and "The Louse in its Relation to Disease" (No. 2), lately published by the trustees of the British Museum. An account, still more condensed, of "The Danger of Disease from Flies and Lice" has now been issued as a four-page Economic Leaflet (No. 1) by the trustees. The life-histories and habits of the insects are dealt with as effectively as possible in the small space allowed, and practical directions for their extermination or for the prevention of their infective activities are clearly given.

THE latest number (No. 2, of vol. vi.) of the Bulletin of Entomological Research is of larger size than usual, and contains at least three papers of importance. Prof. M. Bezzi describes with clear structural figures the Ethiopian fruit-flies of the genus Dacus. Mr. F. V. Theobald contributes part 2 of his enumeration of African Aphididæ, diagnosing and figuring many new species, and founding three new genera. It is of interest to know that common European species, such as *Macrosophum pisi, M. sonchi,* and *Lachnus viminalis,* are to be found in Egypt, and the first-named in British East Africa also. Incidentally, Mr. Theobald furnishes a table for the discrimination of all the rose-feeding aphids known to him. Mr. A. T. Stanton describes, with illustrations of external features, the larvæ of thirteen Malayan Anopheline mosquitoes.

A BULLETIN (No. 8, 1915) issued by the Department of Fisheries for the Indian provinces of Bengal and Bihar and Orissa deals with the statistics of fish caught during the year 1912–13. Mr. T. Southwell refers to the undoubted fact that the supply of fish in the United Province is diminishing. Fresh-water fisheries are certainly exhaustible, and in this case irrigation schemes have produced changes which have led to diminution of the natural resources. The remedy, he indicates, lies in artificial cultivation, basing this procedure upon the scientific knowledge of the natural history of the staple species now gradually being obtained by the Department. Artificial culture, he says, will not be a difficult task, but it will

be difficult so to organise this work that restocking of the rivers, *beels*, and tanks of the province may proceed rapidly under the new conditions. Economic difficulties will further hamper the improvement of the fisheries, but there is much hope for progress in the fact that the Department of Fisheries is a growing one, basing its administrative work upon a foundation of scientific investigation.

THE Gardens Bulletin of the Straits Settlements, No. 9, vol. i., contains among other notes three papers on yams, one of which, on the sprouting of the tubers of *Dioscorea alata*, is of general botanical interest. It has been known for some time that the tubers of yams sprout more quickly from the basal or older portions than from the younger, and that if a tuber be halved the shoots are usually produced towards the base of either half, and most quickly from the base of the oldest half. Mr. Burkill has made a careful series of experiments with tubers cut up into sets, and has recorded in tabular form the date of the appearance of the sprouts from the different sets. The results are in agreement with expectation, but it is found that different races vary considerably in the precocity or lateness of their sprouting.

MR. E. D. MERRILL continues his studies on Philippine botany in No. 4 of vol. x. of the *Philippine Journal of Science* with an account of the Anonaceæ of the islands. The family is well represented in the Philippines, and twenty-four new species are described in the present paper. The genus Papaulthia, recently described by Diels from material collected in New Guinea, is found to be represented in the Philippines by six species formerly included under Polyalthia and Unona. *Papaulthia mariannae*, described by Safford, from the Mariana Islands, is considered by Merrill to be the type of a new genus Guamia, allied to Oncodostigma rather than to Papaulthia. The genera Desmos, Dasymaschalon, Griffithianus, Meiogyne, and Pseuduvaria are also new to the flora of the islands.

THE issue of a catalogue by Messrs. J. Wheldon and Co., devoted exclusively to agriculture, serves as a reminder of the number and value of agricultural books that have appeared from time to time in this country, and particularly in the eighteenth and early nineteenth centuries. The catalogue includes the thirteenth-century Walter of Henley's "Husbandry" (1890 reprint), Fitzherbert's "Book of Husbandry" (Skeat's reprint), and typical works by most of the well-known writers that followed—Tusser, Blith, Ellis, Bradley, and, to come to the end of the eighteenth and beginning of the last century, Young and Marshall. Among the most interesting items are a long series of the Annals of Agriculture, a complete set of the octavo volumes describing the survey of England and Wales made by the Board of Agriculture during the years 1795–1815, and an almost complete set describing the Scotch survey. The prices serve to remind us that the old agricultural books are becoming scarcer; it is notorious that many of them have in the past found their way over to the United States. Indeed, the agricultural expert who has hitherto wanted to consult agricultural literature, either old or new, has had no little difficulty, and he has been very unfavourably situated in comparison with the chemist or the botanist, who could always go to the library of the Chemical, the Linnean, or the Royal Society. It is hoped that the new library at Rothamsted, when it is developed, will remedy this defect.

THE monthly meteorological charts of the North Atlantic appear with regularity, and contain much useful information. In the November issue an account is given of the severe cyclone which devastated the north side of Jamaica on August 12. Details are promised later, but from the information to hand it appears that the storm centre passed fifty miles north of Jamaica, after devastating the south of Haiti. On August 16 it reached Galveston, where the wind attained ninety miles an hour. The disturbance was fifteen hours in transit. On the 17th it passed south of Houston, and continued north-west. On the 18th it recurved in 32° N. 98° W., and proceeded towards the St. Lawrence valley, where it died out in about 47° N., 74° W. on August 23rd. All along its track, but especially in Texan ports, considerable damage was done, and many lives lost. The greater part of the banana plantations in Jamaica was destroyed, but the coconut trees seem in great measure to have escaped.

THE October number of the Journal of the Franklin Institute contains an article by Dr. H. E. Ives, of the Physical Laboratory of the United Gas Improvement Company of Philadephia, describing the apparatus he exhibited before the American Physical Society a year ago for simplifying photometry and placing it on a firmer physical basis. Light as one of the forms of radiation should be measured in ergs per second or in watts, and not in terms of an abitrary unit, like the lumen. The instruments for measuring radiation are, however, sensitive to radiations which produce only a partial or no luminous sensation in the average eye. It is therefore necessary to interpose between these instruments and the luminous source an absorbing substance which will transmit of each type of radiation a fraction proportional to the sensitiveness of the normal eye for that type. Such a substance combined with a thermopile or bolometer and a galvanometer would constitute an artificial eye, and the deflections of the galvanometer would be proportional to the light entering the eye. Dr. Ives recommends as the absorbing substance a layer one centimetre thick of a solution containing 60 grams cupric chloride, 14 cobalt ammonium sulphate, 1·9 potassium chromate, and 18 c.c. nitric acid to the litre. A layer of water 2 cm. thick should be interposed between the source and the solution.

AN interesting account of the potash mines in Alsace, which helps to give a true perspective of the part they are likely to play in the future production of the world's supply of potash, is contained in a short article in *La Nature* of October 2, p. 220. The value of these mines has undoubtedly been greatly exaggerated by the newspaper Press, but none the less, they are of great and real significance. As regards the scheme of nationalisation which has been frequently mooted,

it is pointed out that already 45 per cent. of the shares are held by Alsatians or Frenchmen, so that such a scheme is scarcely legitimate. Under the German *régime* the part reserved to the Alsatian mines by the *Kalisyndikat* of Stassfurt represented only 10 per cent. of the total sales, although a policy of free competition would have justified a far greater output. It is, however, probable that after the war arrangements will be made allotting to the Alsatian mines at least 25 per cent. of the total world's supply. The development of the Catalonian mines may modify this figure, but the development in this field promises to be slow.

WE have received a copy of the first issue of the Journal of the Association of Official Agricultural Chemists (Baltimore, U.S.A.: Williams and Wilkins Co.), of which the Syndics of the Cambridge University Press have undertaken the agency in the British Empire. The journal will be the official medium for the presentation of data and analyses in the domain of agricultural chemistry, and will include the proceedings of the association, reports of scientific research, and complete statements of the official methods. Until recently the work of the association has been included in special bulletins published by the Bureau of Chemistry of the U.S. Department for Agriculture; the publication in journal form will make this work available to a large public. The purpose of the association is to secure uniformity and accuracy in the methods, results, modes of statement of analysis of fertilisers, soils, foods, dairy products, medicinal plants, drugs, and other matters connected with agricultural industry. The journal, therefore, is of importance to the chemist, the agriculturist, and the manufacturer. It will be published quarterly, and each volume will consist of about 600 pages. The subscription price is 23*s*., post free. Subscriptions may be sent to Mr. C. F. Clay, Cambridge University Press.

EVERY engineer who, since the war began, has taken up the manufacture of war material has found himself hampered, and his output delayed, by the Woolwich regulations for inspection and gauging. The leading article in the *Engineer* for October 29 gives an interesting example of regulations which might be relaxed in the present circumstances. In the manufacture of steel bars for shells, the Government brand is put upon the material at every stage of its progress. The cast ingot is stamped, then the billet, and then the bar rolled from it. From the bar a dozen or more separate pieces, each to make a single shell, have to be cut. The brand is stamped upon the side of each piece before it is cut off. Rough turning removes it, and it has to be renewed on the base, then the base is cut away, and the brand has to be put on the side. In peace time this was splendid—the identity of every shell was preserved. At present there is no reason for keeping this close watch on every piece, and the final test stultifies the whole. Only one shell is drawn from a mixed batch of five hundred, and tested by firing from a gun. If it fails the whole mixed batch may be condemned. There are several other cases which might be quoted in which system appears to have run away with intelligence.

MESSRS. T. C. AND E. C. JACK (London and Edinburgh) have in preparation for their "Through the Eye" series:—"The Evolution of the Plant," by Dr. H. F. Wernham; "Greek Civilization," by Prof. J. S. Phillimore; "Bird Life," by W. P. Pycraft; "The Evolution of the Bird," by W. P. Pycraft; "Roman Civilization," by A. F. Giles.

OUR ASTRONOMICAL COLUMN.

VARIABILITY OF α ORIONIS.—In the current number of the *Observatory* Mr. F. W. Backhouse directs attention to the abnormally diminished brightness of this star. On October 14 it appears to have been 0·5 magnitude—one magnitude fainter than usual.

THE SOLAR CONSTANT.—Criticism of the extremely accordant determinations of the solar radiation made under the auspices of the Smithsonian Astrophysical Observatory has been based almost entirely on the amount of the correction for the effect of the terrestrial atmosphere. Prof. Very maintains that the Smithsonian observers underestimate this effect, consequently obtaining a value much too low. Although the Langley method has already been applied under a diversity of conditions—height above sea-level, atmospheric transparency, temperature, etc.—yielding satisfactorily harmonious results, yet unceasing efforts have been made to apply more and more severe tests by carrying out the measures under the least possible superincumbent air-mass. The most effective way in which this can be accomplished is by raising self-recording instruments to the greatest possible height in the atmosphere by means of free sounding balloons. An account of the most recent experiments of this kind is presented by Messrs. Abbott, Fowle, and Aldrich in a memoir (Smithsonian Misc. Coll., vol. lxv., No. 4, 1915), which forms an important contribution to the subject. Space only permits a hint at the ingenious instrumental devices embodied in the apparatus, the searching laboratory tests, and the manifold corrections involved in the reductions. The most successful day ascent was made on July 11, 1914, from Omaha. At a mean altitude of 22,000 metres (nearly fourteen miles) the three best records gave 1·76 Calories per sq. cm. per minute. Corrected to mean solar distance, etc., this becomes 1·84 Calories. The barometric record indicated a pressure of about 3 cm. of mercury (*i.e.* about 1/25 normal atmospheric pressure. Other pyrheliometric measures have been made at heights corresponding to pressures of 30 cm. (manned balloon, Dr. Peppler), 44 cm. (Mt. Whitney), and 62 cm. (Mt. Wilson). These records, with the maximum value observed by Dr. Kimball at Washington, when plotted lie quite close to a straight line. It is concluded that the Smithsonian value (1·93 Calories) for the constant of solar radiation outside the atmosphere is amply confirmed.

PROPER MOTIONS OF STARS IN THE REGION OF N.G.C. 6705.—Recently M. Comas Sola announced the discovery of a number of large proper motions in the region of this cluster (Messier 11) by stereoscopic examination of photographs. In view of the considerable interest recently aroused in this and allied methods of rapidly determining proper motions (see various notes in this column, also in the current number of the *Observatory*), it is important to note that Prof. E. E. Barnard (*Comptes rendus*, vol. clxi., p. 411) has examined the region of this cluster in the stereocomparator. Although the pair of plates were separated by an interval of twenty-two years (approxi-

mately seven times the interval between M. Sola's plates) no stars showing movement could be detected.

THE FUTURE OF THE PLANETS.—Under this title M. P. Puiseux contributes an essay to *Scientia* (October) dealing with some possible consequences of the explosion hypothesis due to Mr. R. T. A. Innes. The underlying idea is that sufficiently great pressure may be capable of inducing an explosive instability of the elementary atoms of matter resembling the transformations associated with radio-activity. If this is a fact of nature, then condensing stellar bodies become spontaneously explosive. It is supposed that the destruction of the planets will be brought about by a solar outburst of this character.

AMERICAN HYDROLOGY.[1]

THE issue by the United States Geological Survey of a further instalment of water supply papers directs attention to the continued activity of that department in prosecuting its researches into the national water resources available for industrial and agricultural purposes. The papers cover an extensive area of country and a diversity of subjects; and accordingly it will be convenient to deal with them seriatim.

(1) The eastern and southern coasts of the United States and the contiguous parts of Mexico and Central America, as far as the peninsula of Yucatan, constitute a broad, sub-level region, sloping gently seaward from the interior highlands. In the basin of the Mississippi, this plain, known as the Gulf Coastal Plain, extends inland for a distance of no fewer than 500 miles. This, however, is the maximum breadth. On the Atlantic coast and in Mexico it is much more restricted, reaching mountainous districts at no great distance from the sea. The plain is characterised generally by low relief and broad river valleys, and in Texas, with which region Mr. Deussen's report is specially concerned, it comprises a series of prairies and wolds, the latter term denoting a range of hills sloping gently on one side and descending abruptly on the other.

Being a hydrographical paper, the report is drawn up from the point of view of defining and classifying the available sources of water supply, and accordingly the stratigraphy of the various districts is described in relation to their water-producing powers. The geological systems represented are the Carboniferous, the Cretaceous, the Tertiary, and the Quaternary. The Carboniferous rocks are not exposed, nor have they been reached by any boring within the limits of the area under consideration, but their presence is inferred from an exposure further west, and by the evidence of drill-holes in the adjacent Cretaceous area. The Cretaceous rocks, which consist for the most part of chalk, limestone, and marl, are so deeply embedded as to render them impracticable as sources of supply, either by artesian wells or otherwise. The available water-bearing strata are, therefore, the sediments of the Tertiary and Quaternary series, comprising some dozen formations, of which may be noted the Dewitt (Miocene), 1250 to 1500 ft. thick, and the Wilcox (Eocene), 800 to 1150 ft. thick. The former consists of lacustrine and littoral deposits: cross-bedded, coarse, grey, semi-indurated, highly calcareous sandstones; and the latter of palustrine, marine, and littoral sands, clays, marl, and lignite. The waters from these sources are classified and analysed according to their locality and occurrence.

(2 and 3). The next two papers deal with the chemical side of water supply. They exhibit in tabular form the constituents of samples of water, taken from various sources in the United States, and submitted to chemical analysis, together with some useful notes as to the bearing of chemical composition on the suitability of such waters for specific purposes. Most of the waters are commonplace in character, but some are exceptional; for instance, the Devil's Inkpot in the Yellowstone Park is essentially a solution of ammonium sulphate, and the Shoal Creek springs in Missouri are impregnated with zinc to a remarkable degree.

The physiographical features of the State of Washington are described at some length in Mr. Van Winkle's report, and it is interesting to note that the Cascade Range of mountains, which crosses the State from north to south, divides it into two regions with very dissimilar climatic conditions, that on the western side characterised by an abundant rainfall, with cool summers and mild winters, and that on the eastern side by a moderate, and even scanty, rainfall, with hot summers and cold winters.

(4) The Deschutes River is a tributary of the Columbia River, entering the latter at a point about 135 miles above the town of Portland. It is stated that the river is unique in several respects among rivers of the United States. "Its natural flow is remarkably constant; its head waters afford reservoir sites sufficiently large and so distributed that the total flow of the river may be utilised both for irrigation and for power"—these features, combined with the suitability of the river basin for their practical application, justify the expectation that the Deschutes Valley will become a flourishing district of agricultural importance, enhanced by numerous installations of hydro-electric plant furnishing power, either locally or for transmission to distant distributing centres.

(5) The rugged region of western Montana includes a curious re-entrant of the Continental Divide, forming a basin, bounded on the north, east, and south sides, and on part of the west side, by mountain walls. This basin, the flat floor of which is a little more than a mile above sea-level, has a maximum length of twenty-two miles, a maximum width of ten miles, and an area of 130 square miles. It probably came into existence near the close of the Tertiary or at the beginning of the Quaternary period. It is noteworthy to-day as containing on its northern side the Butte mining district, the most important mining centre in the United States. Started in 1864, when placer gold was discovered in the locality, the settlement has grown to a town of more than 50,000 inhabitants. The effect of this invasion of human activity has been to change completely the natural aspect of the place. The mountain sides have been denuded of their trees and the valley floor of its luxurious vegetation by sulphurous fumes emitted in great clouds from the smelting works, and a scene of desolation and ugliness has supervened. Since 1912, however, conditions have somewhat improved. Most of the large smelters have been shut down or removed, and the citizens are endeavouring by the cultivation of lawns, gardens, and trees, to restore something of the original beauty of the valley. The climate is somewhat rigorous, the mean annual temperature being 42° F., and the lowest recorded temperature 29° F. below zero. The water supply of the district is plentiful; there is an average daily consumption of nine million gallons for 55,000

[1] (1) Geology and Underground Waters of the South-Eastern Part of the Texas Coastal Plain (Water Supply Paper No. 335). By Alexander Deussen. Pp. 365, with diagram and ix plates.

(2) Water Analyses from the Laboratory of the United States Geological Survey (Water Supply Paper No. 364). Tabulated by J. W. Clarke, Chief Chemist. Pp. 40.

(3) Quality of the Surface Waters of Washington (Water Supply Paper No. 339). By Walton Van Winkle. Pp. 105, with charts.

(4) Deschutes River, Oregon, and its Utilisation (Water Supply Paper No. 344). By F. F. Henshaw, John H. Lewis, and E. J. McCaustland. Pp. 200, with 28 plates and 8 diagrams.

(5) The Water Resources of Butte, Montana (Water Supply Paper No. 345-G). By O. E. Meinzer. Pp. 125, with map and photographs.

persons, or 165 gallons per head, which is a very liberal allowance compared with the customary consumption of large towns in this country. The figure is stated to include considerable quantities used by mines, railroads, and other industrial concerns, but even then it is greatly in excess of the standard prevailing in the United Kingdom. B. C.

ENGINEERING AT THE BRITISH ASSOCIATION.

SECTION G (engineering) had a very full programme, which necessitated carrying the meeting on until mid-day on Saturday, September 11. The papers were grouped as follows: after the president's address by Dr. Hele-Shaw on Wednesday, the morning was devoted to papers dealing with thermodynamics. The following morning was set apart for papers by local engineers, describing recent work in the various departments of municipal engineering (electric, gas, drainage, etc.); the papers read on Friday were all connected with electrical engineering, while Saturday morning was devoted to mechanical engineering.

Wednesday, September 8.—In his address the president insisted on the duty of the British Association to justify its existence by doing something tangible to help the Empire in the great industrial struggle which must ensue when the military struggle comes to an end. He advocated the formation of a committee, initially of the engineering section, not merely to offer its services to any Government department, but to consider and urge the initiation of those reforms which would strengthen our hands in the coming international industrial warfare. The first paper was by Profs. Asakawa and Petavel, describing a series of experiments on the efficiency and losses of a gas engine; a preliminary note on the subject was presented at the Birmingham meeting two years ago. The authors have determined the overall efficiency and the magnitude of the various losses with different mixtures and different compression ratios. The highest overall efficiency obtained was 27·4 per cent. The mechanical losses were determined by the rate of change of the kinetic energy of the rotating parts, as is very commonly done in testing electric motors.

Prof. W. M. Thornton gave two short papers of a theoretical and speculative nature, entitled "The Total Radiation from a Gaseous Explosion" and "The Change of the Specific Heat of Gases with Temperature." According to the author, the lost pressure or suppressed heat of a gaseous explosion can be explained mechanically by considering two combining atoms to act like colliding spheres. Their translational energy will generally be converted partly into vibrational and partly into rotational energy. Assuming that before the collision the translational and rotational energies of the atoms were equal, and that on collision the former is equally converted into rotational and vibrational, the latter, on which depends the radiation, will represent 25 per cent. of the total, which result the author claims to be in agreement with the observations of Hopkinson and David.

On Wednesday afternoon at the laboratories of the Manchester Steam Users' Association, Mr. C. E. Stromeyer explained and demonstrated a machine for determining the fatigue limits calorimetrically. In this machine the specimen, which is subjected to rapidly reversed torsion, tension, or bending stresses, is water-jacketed, and the temperature of the water passing through the jacket is measured on entering and on leaving. No difference is detected until the stress reaches the fatigue limit for the specimen under test, but as soon as this is passed, heating of the jacket water takes place. Hence the fatigue limit is determined by gradually increasing the stress and watching the two thermometers.

Mr. Stromeyer also gave a demonstration of the phenomenon of water hammer by means of gas-heated glass vessels and tubes.

Thursday, September 9.—Mr. de Courcey Meade, the corporation engineer, read a paper on the Manchester drainage scheme, and showed a number of lantern slides illustrating the special work in connection with the new sewers now under construction. He was followed by Mr. S. L. Pearce, the corporation electrical engineer, who outlined the growth of the electrical undertaking and then described the general outlines of the projected station at Barton on the Bridgewater Canal. When completed, this station, which at present exists on paper only, will be one of the largest in the country. It will transmit three-phase power at 33,000 volts to a number of substations. An interesting point is that the site is in close proximity to the corporation sewage works at Davyhulme, and it is proposed to use the purified effluent for condensing purposes, the canal authorities having refused permission to use the canal water. The increased temperature of the sewage effluent after passing through the condensers is advantageous in the further treatment before final discharge.

Prof. A. B. Field described the special research work which is being carried out in the mechanical engineering department of the Municipal School of Technology, which was afterwards visited by the members of the Section.

The corporation gas engineer, Mr. J. C. Newbigging, described the improvements recently introduced by the adoption of automatic vertical retorts; he also attacked the system of applying the profits from municipal gas undertakings to the relief of rates, instead of lowering the price of gas and thereby increasing its adoption for heating and power purposes. It need scarcely be said that this part of his paper did not go unchallenged in the discussion, dealing, as it does, with one of the thorniest problems of municipal politics.

A paper was read by Mr. E. C. Mills describing his producer for placing in front of an ordinary steam boiler. The gasification of the fuel is carried out in this external producer, while the combustion of the gas takes place inside the ordinary boiler flue. Slides were shown and actual test figures given for boilers which had been fitted with the apparatus.

Friday, September 10.—Mr. N. W. McLachlan showed experimentally the rapid heating of iron strips when magnetised by high-frequency currents obtained from an arc-generator. The variation of permeability with temperature and the points of recalescence could be traced in the variation of the current taken by the magnetising coil. The phenomena are complicated, however, by the skin effect, the depth of penetration varying with the temperature due to the changes in both resistance and permeability.

A self-adjusting commutating device was described by Prof. Miles Walker, in which each brush is divided into two, one in advance of the other, the two being lightly insulated from each other. Before combining, the current from one brush passes round the interpole winding, while that from the other passes through an equivalent resistance. If the commutation be perfect, the current density will be uniform over the whole brush contact surface, and each brush will collect half the total current; if, however, on account of saturation at heavy loads, the strength of the interpole be insufficient, the commutation will be so affected that a larger share of the total current will pass through the interpole winding, increasing

its flux, and thus compensating for the saturation. This device should prove especially useful in the case of rotary converters, where the commutation is often difficult; it will enable an increased output to be obtained from a machine of a given size.

A mathematical paper on "Electric Oscillations in Coupled Circuits" was read by Dr. Eccles and Mr. A. J. Makower. The special case considered was that in which three paths, each containing an inductance and a condenser, are connected in parallel. The formulæ obtained were confirmed by tests in two simple special cases, viz., two tuned circuits coupled either by a common condenser or a common inductance. In the discussion Prof. Howe showed that the two special cases dealt with experimentally could be calculated in a very simple manner by a suitable choice of initial conditions.

Prof. G. W. O. Howe then read a paper on "The Capacity of Aerials of the Umbrella Type," in which the method described by the author at the Sydney meeting last year was extended to aerials of this type. In the discussion Prof. Schuster pointed out that the small error due to the author's assumption of a uniformly distributed charge would be always in the same direction.

A note on "Earth Resistance" was read by Prof. E. W. Marchant, who suggested the use of the equivalent length of a column of the earthy material, which, with a cross-section equal to the surface of the buried conductor, would have the same resistance as the actual earth, as a criterion of the "earth." Prof. Howe showed that this "equivalent length" depended merely on the dimensions, and need not be determined experimentally, since such measurements depended on the uncertain specific resistance of the soil; it could be calculated in the same way as the capacity, if the conductors were surrounded by an insulating medium. Dr. Eccles pointed out the need for caution in applying the continuous or low frequency resistance to the case of a radio-telegraphic aerial.

Messrs. Lacey and Stubbings described some experiments to determine the effect of a third harmonic on the iron losses of a three-phase transformer, the harmonic being due to the saturation of the cores. With a triple harmonic of 48 per cent. the iron loss decreased 22·5 per cent. on opening the neutral wire; this would prevent any third harmonic in the current and would remove the sine-wave constraint from the magnetic flux, which would consequently reach a lower maximum value.

Prof. E. Wilson gave further information about a number of aluminium alloys, which have been exposed on the roof in London for many years, and on which he has reported on previous occasions.

Saturday, September 11.—Mr. T. H. Brigg described a new method of attaching horses to vehicles, the principle of which is that the shafts are forced upward by a spring, thus relieving the horse of a part of his own weight when travelling on an easy road. As soon as the road becomes more difficult, owing, say, to an up gradient, the increased pull on the traces overcomes the spring and exerts a downward force on the shafts, enabling the horse to obtain the necessary adhesion on the road.

The report of the committee on complex stress distribution was read by Prof. Coker. It consisted mainly of a comparison of the behaviour of a sample of mild steel when subjected to steady and alternating stresses respectively.

A paper on the strength of iron and steel struts was read by Mr. A. Robertson. It was a record of experiments on solid, free-ended, centrally-loaded struts made at Manchester University. The results confirmed Euler's formula, except for very short struts; the latter are discussed in detail in the paper.

Prof. C. Batho described a new method of determining the torsion stresses in framed structures and thin-walled prisms, especially useful in the case of cantilever bridges in which the suspended span is subjected to torsion, owing to unsymmetrical loading on the cantilever and anchor arms. The author showed the application of the method to a bridge of similar design to the new Quebec bridge.

Prof. Miles Walker described some experiments made to determine whether the acceleration of one mass exerts any force on a neighbouring mass, as it should do if the analogy between the electric current and the movement of matter be perfect. The results obtained were negative, although the apparatus combined great sensitiveness with the very rapid acceleration of large masses. Prof. Schuster expressed regret that a paper of such physical importance had not also been brought before Section A (Physics) of the Association.

This brought the proceedings of Section G to a close.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

IN Section H (Anthropology) the proceedings showed little departure from the normal except perhaps in the small number of ethnographical papers, and in the character of the discussions which, on the whole, were a little less vigorous than usual, owing to the absence of many who, as a rule, may be counted upon to take part in the debates. The programme, however, showed a longer list of communications than might have been expected.

As in other sections, subjects of special interest at the moment were not neglected. Indeed, the principal item in the programme was a discussion which took place in joint session with Section E (Geography) on "Racial Distribution in the Balkans." This was opened by Prof. G. Elliot Smith, who, after a lucid exposition of the geographical, ethnological, and historical factors which have brought about the segregations and disunion of the Balkan peoples, went on to show that in spite of conflicting interests arising out of differences of history and creed, ethnological no less than geographical and economic considerations definitely linked together the Slovenes, Croats, and Serbs as one race, whose domain included not only Croatia (with Slavonia), Bosnia, Herzegovina, Montenegro, and most of Serbia as at present delimited, but also Dalmatia, nine-tenths of Istria (excepting Trieste), Carniola, and a strip of South Hungary. On ethnological grounds Bulgaria had a greater right than Serbia to the part of Macedonia now in occupation by the latter, and on racial grounds her claim to the Dobrudja was more justifiable than that of Rumania. Sir Arthur Evans exhibited a diagrammatic map illustrating the ethnic relations between the Adriatic, the Drave, and the Danube, the result of many years' observations in the area which is now occupied by the southern Slavs or Jugo-Slavs. Ethnological considerations supported the argument for a Jugo-Slav State. Italic preponderance was situated in the lower valley of the Isonzo, at Trieste, and in Istria. In Dalmatia, except in the town of Zara, the Italian element amounted to about 3 per cent. only of the population, the prevalence of Italian culture and the use of the language for commercial purposes giving a wrong impression. Sir Arthur then pointed out the value of the establishment of such a state in facilitating the completion of a railway, joining up

east and west along the main Roman road from Aquileia to Nissus, and running from Milan to Nish through Gradisca, Laibach, and Belgrade. The Hon. W. Pember Reeves, who was unable to attend the discussion, sent a communication in which, in dealing with the position of the Greeks, he urged that on historical and ethnological grounds their present northern boundary, including Epirus, corresponded closely to the ideal; while in Macedonia the line dividing the Bulgar-Slav portion from the Greek drawn by the Treaty of Bukarest represented the facts, especially as since the war of 1912–13 much migration had taken place on each side of the line. The claims of Greece to Bulgarian Thrace were justifiable on economic rather than ethnic grounds; on the other hand, the claim of Bulgaria to the eastern part of Macedonia was stronger than that of Serbia. In Monastir the existence of Vlach, Bulgarian, and Greek elements gave rise to a separate problem. It is scarcely necessary to emphasise the fact, upon which stress was laid by each speaker in turn, that political considerations had no part in the discussion.

Another matter of topical interest was the subject of a communication by Prof. Arthur Keith. In 1905 Prof. E. Manouvrier, of Paris, published a paper entitled "Une Application Anthropologique à l'Art Militaire: le Classement des Hommes et la Marche dans l'Infanterie," in which he advocated the classification of soldiers according to length of the lower limbs, rather than according to height, in order to minimise fatigue. This publication had not received attention in this country at the time of its publication, and a summary of its contents was now presented to the section at the request of the author. In the discussion which followed the hope was expressed that the suggestions might be put to a practical test.

A second discussion had for its subject "The Influence of Egyptian Civilisation on the World's Culture." It was opened by Prof. Elliot Smith and Mr. Perry. Their communications covered a wide field. They argued that towards the close of the new Empire a great many of the most distinctive practices of Egyptian civilisation, carried possibly in part by Phœnicians, suddenly appeared in the more distant parts of the coast lines of Africa, Europe, and Asia, and in course of time in Oceania and America. Mr. Perry relied in particular on the association of megalithic buildings and mine workings, or the situation of such monuments in or near regions noted for gold, precious stones, or pearl fisheries, as well as on similarities of technique in smelting or refining operations. In the discussion which followed, the opening speakers were subjected to some severe criticism. Sir Arthur Evans, while feeling that it was impossible to discuss adequately a subject of such vast extent, attacked their method of dealing with the evidence, and Prof. Petrie emphasised the necessity for greater precision in dating the facts with which they dealt. Sir Richard Temple pointed out certain difficulties in this connection in the treatment of the Indian evidence. Dr. Rivers, in supporting the openers, explained the reasons which had led him to modify his previous opposition to their position. The president pointed out that the difficulty of the length of time necessary for such a diffusion of culture was perhaps not so great as might be thought; a complete change had taken place in the diet of the native of South Africa since the discovery of America, when maize was introduced to the Old World.

Other communications, in addition to this discussion, also dealt with Egyptian archæology. Mr. Robert Mond made a valuable contribution to the method of recording archæological discoveries with an exhibit of a cardboard folding model of the Theban temple of Menna at Gurnah, on which photographs recorded all the scenes painted on the walls of the two chambers exactly in the position in which they were found. He proposes to survey all the temples and buildings of ancient Egypt in the same manner. Prof. Petrie described the magnificent find of twelfth-century jewelry of a princess, daughter of Senusert III., found by the British School of Archæology in Egypt at Lahun, which is in some respects finer than any yet known.

What was, however, felt to be one of the most important communications made to the section in the course of the meeting was a paper by Dr. E. A. Gardiner, "Fresh Light on the Origin of the Semitic Alphabet," which dealt with inscriptions of Pharaonic date in an unknown writing discovered by Prof. Petrie in Sinai in 1905. The inscriptions would appear to be alphabetic. A detailed analysis supported the conjecture that the system was related to, if it did not actually represent, the common parent of the Phœnician, Greek, and Sabæan alphabets. This Proto-Semitic alphabet apparently was hieroglyphic and acrophonic, *i.e.* the value of the letters was taken from the names of the things they represented.

Sir Arthur J. Evans, following Dr. Gardiner, dwelt upon the value for comparative purposes of the Cretan analogies for the origin of the alphabet, which were decisive against De Rougé's theory that the Semitic alphabet was derived from hieratic Egyptian forms representing similar sounds but having no reference to the actual meaning of the later name. To a certain extent the Minoan and Cretan forms appeared to belong to related systems. Dr. Gardiner's evidence tended to show that Semitic letters were derived from an indigenous source, and if the early forms went back to 1500 B.C. they could not have been introduced from Crete by Phœnicians. Nor did the ***aleph-beth*** theory of Gesenius require Egyptian influence, though it might have been present in both Semitic and Minoan as a formative element.

An interesting paper by Prof. R. S. Conway dealt with the religion and linguistics of early Italy. He described some votive offerings to the Venetic goddess Rehtia discovered on the site of a temple at Este, the ancient Atesta, about eighteen miles south of Padua. The offerings, which were of two classes, consisted of votive nails and wedges recalling Horace's description of *Dira Necessitas*, and bronze tablets divided into longitudinal bands, ten or twelve in number. The latter, the author suggested, might be connected with a game, and possibly were offerings of lucky players.

Two communications dealt with British archæology. The first, by Mr. J. P. Bushe-Fox, described the excavations at Uriconium in the year 1912–14. The finds included a large amount of pottery, evidence of industrial occupations, and a building of unique form. The second, by the Rev. Dr. Dukinfield Astley, on "Early Man in Norfolk," discussed the further evidence for the existence of Aurignacian man in East Anglia furnished by the results of excavations in Norfolk undertaken in 1914.

Among the papers dealing with social organisation and religion was an important communication by Dr. W. H. R. Rivers, on "Ceremonial and Descent in Ambrim," which adduced evidence to show that though at the present time the institutions of the island are patrilineal, in the older ceremonial, which is indigenous, the mother's brother comes into prominence. Consequently in this part of Melanesia it would appear that matrilineal institutions preceded the patrilineal.

Miss Margaret Murray, in her paper on "Royal Marriage and Matrilineal Descent," dealt with the

custom of sister marriage in the royal Egyptian and Semitic families, which, as she pointed out, were not regarded as unusual when recorded by native historians, and traced the customs to a more prolonged survival of inheritance in the female line in royal families. Dr. Nadine Ivanitzky's communication on "The System of Kinship among Primitive Races in connection with their Mode of Grouping" dealt with the manner in which economic and social factors act and react on the recognition of kinship in a group by determining the size of a group, its relation to other and competing groups, and the relation of the individuals within the group.

In physical anthropology, in addition to the paper by Prof. Keith, to which reference has already been made, Dr. Manson exhibited photographs and skiagraphs of members of a family showing hereditary syndactalism and polydactalism, and Dr. G. W. Hambleton discussed chest types in man in relation to disease. Prof. Guiffrida-Ruggeri's "Notes on the Neolithic Egyptians and Ethiopians." criticising the theories of Prof. Elliot Smith and others on the physical affinities of the early inhabitants of Egypt, and Prof. Elliot Smith's communication on "The Earliest Human Remains from India," owing to lack of time, were taken as read.

At the close of the proceedings, the section, at the invitation of the Ribchester Museum Committee, visited the Roman camp at Ribchester for the formal opening by Prof. F. J. Haverfield of the recently completed Museum of Roman Antiquities. Prof. Haverfield then delivered an address on the purpose of the small *castella* or forts, found scattered over all the north from Chester to Carlisle and from the vale of York to Tyneside, of which Ribchester is an example, as purely military units controlling the country from strategic points.

THE RELATION OF EDUCATION TO INDUSTRY.[1]

AT the last meeting of the British Association in Manchester, in 1887, the president, Sir Henry Roscoe, in his opening address, referred to national education with patriotic candour, in the following prophetic sentence:—"The country is beginning to see that if she is to maintain her own commercial and industrial supremacy the education of the people from top to bottom must be carried out on new lines. The question as to how this can be most safely and securely accomplished is one of transcendent national importance, and the statesman who solves this educational problem will earn the gratitude of generations yet to come."

A generation has passed since Sir Henry Roscoe uttered his prophecy, and still our national education is, though improved, far from being carried out on the principles and methods which will ensure our industrial supremacy. In other words, "the statesman" has not yet appeared!

By national education we mean, of course, the education of the whole people, not of a class only. From 1872 until as late as 1889 no attempt was made by Government to provide secondary and technical education in continuation of the elementary stage, and in consequence of this the progress made in scientific knowledge bearing on industry and commerce was withheld from our own people who most needed it, and left to other nations who were better qualified to reap the advantage. The results, it is well known, have been lamentable, for it so happened that it was during this very period that the most remarkable discoveries and development in science were revealed to the world, and their practical application demonstrated. During that period, and indeed long before, notably in Faraday's lifetime, England produced some of the most eminent men of science in the world, who opened out to us the immeasurable possibilities of adding to the material wealth and prosperity of our country by the adoption of their discoveries.

Only two countries, however, were ready to take practical advantage of these discoveries owing to their widespread facilities for education ranging through the elementary to secondary and technical schools up to scientific teaching in the universities. These countries were America and Germany.

Consequently the great discoveries relating to the utilisation of those subtle forces of electricity and magnetism achieved their first triumphs in these two countries, where the spirit of education had long before penetrated the lives of the people and prepared them to adopt and apply the new revelations of science to the common needs of human life.

These great movements stirred our Government at last to send out a Royal Commission to investigate the educational facilities in the secondary and technical schools of foreign countries. Oh, the pity of it! That a country which had enjoyed the greatest opportunities for the application of scientific discoveries and methods to industry through the undisturbed monopoly of engineering, chemical, and other industries extending over a full century, should have neglected the only means of retaining that position by the adoption, during the years of expanding wealth and prosperity, of a system of universal, free, and enlightened education open to every class throughout the land! The reports brought back from Europe by the Royal Commission, and one from America, written by myself after eight months' investigation, spread alarm throughout the United Kingdom and the British Empire. These reports were published in 1884. No action was taken by Parliament until 1889, when happily a Technical Instruction Act was passed, within two days of the close of the session, but almost by a fluke even then, owing to the efforts of a few desperate men on both sides of the House who believed that "through lack of knowledge the people perish."

Probably no Act of Parliament was ever seized upon with such avidity as this Technical Instruction Act, for, as the municipalities themselves were by the Act constituted the local administrative authorities, the large manufacturing districts, notably Manchester, Salford, and other parts of Lancashire, were especially eager in pressing for its adoption. The following year the "whisky and beer tax" was earmarked for the support of technical education, which resulted in numerous fine institutions being erected in many parts of the country. In 1902 secondary education was adopted permissively in a new Elementary Education Act, and though not adequate to meet the wants of the country, it was received with thanks for small mercies owing to the fact—which in some other countries would have been foreseen—that no system of thorough technical education can be carried out where secondary education is a missing link, so that for a time our national system of public elementary and technical education minus the secondary was more like "a rope of sand than a chain of welded links."

As a result of the passing of the Technical Instruction Act of 1889, the development of technical instruction was so rapid that in 1895 an Association of Technical Institutes was formed. A large number of new schools have been erected solely for the purpose of technical instruction, and are equal in equipment and staff to the average of those in the United States and

[1] Abridged from a paper read before the Section of Educational Science of the British Association at Manchester on September 11, by the Right Hon. Sir William Mather.

on the Continent. Such, for instance, are the schools of Manchester, Salford, Birmingham, Belfast, Sheffield, Bradford, Bristol, Edinburgh, Nottingham, London, and of these several take rank as technical universities where day students may graduate and recognised degrees may be obtained. In particular, the Imperial College of Science and Technology and the Manchester School of Technology are not surpassed by any similar institution in the world.

There are now eleven universities in England and Wales, including the ancient ones of Oxford, Cambridge, and Durham. The latter have conformed to the spirit of the age by adapting themselves to the requirements of science, while the more modern universities, though primarily established to meet the needs of industrial development, have taken ample care of the equally important subject of the arts.

A general survey of our present equipment for national education would, however, clearly show that we are still far below the standard our industries require if they are to compete successfully with those of other countries; therefore the most reactionary form of economy during the war would be the reduction of Government grants to education of any grade.

It would be noted also that no provision has yet been made to continue the education begun in the elementary schools through the period of adolescence —the impressionable period for good or evil—in the life of our young people who at fourteen years of age must begin to earn something towards their own cost of living. Each year something like 600,000 of these young people leave the elementary schools, forming a population of about two millions of young people, from fourteen to seventeen years of age, a prey to many evil influences, and comparatively few of them are accounted for in the attendances at the evening schools. Special provision for them has not yet been made, nor has any definite system of continuation schools for the manual worker yet been established; consequently the expenditure on public elementary education is largely wasted, and the mental, moral, and physical training of the children of the nation is suddenly arrested at fourteen years of age.

This link in the chain of education is so vitally important from the industrial point of view alone that it should be dealt with without delay by a special committee of industrial and educational experts; for after this war more than ever shall we need to use every advantage that the highest education can confer upon our people in order to utilise the ample material resources of all kinds which we possess, if we wish to maintain our place in the world of industry and commerce.

At this point I will venture to express a doubt as to the efficiency in administration of our national education system at the top, either for initiation or control. A Department of Education, with a Cabinet Minister as president, assisted by a permanent Secretary of Education and a vast number of inspectors and examiners and Civil Service clerks is, in my opinion, unsuitable for our country as well as extremely uneconomical. A bureaucratic spirit creeps into such a Department, without any one person being specially to blame, and such a spirit is the obstacle to enlightened progress.

The freedom and responsibilities of local administrative authorities, acting through competent directors of education and committees composed largely of the best and most enlightened in the community as coopted members, may be, and in fact are, frequently impaired or destroyed altogether.

The glaring inconsistency of the Board of Education, as at present constituted, lies in the political necessity of changing the president at every change of Government. The education of the people of the nation is a subject too sacred to be rendered liable to the whims and caprices of party politics.

A small salaried Council or Royal Commission of Education, appointed by Parliament from the best men the country possesses, regardless of party, each retiring at fixed periods, but eligible for reappointment, would suffice to represent the State in all respects, while ensuring the continuity of principles and methods of progressive education. The local authorities, under such conditions, would undertake large responsibilities with greater freedom, and higher educational efficiency would be assured throughout their respective areas of administration.

One's mind naturally associates the desire for true education chiefly with the industrial classes, and especially so in these times when, under the terrible stress and strain of a vast war, the real qualities of men and things are disclosed. It is obvious that a more thorough and enlightened system of education such as we have been considering would in the course of years render the relations between employer and employed totally free from the troubles we have had and must have from time to time under present conditions.

These disputes arise out of a sense of injury, real or imaginary, on the part of one side or the other, generally in connection with wages and hours of labour, or with questions of discipline and business management. Evidence is accumulating to prove that the relationship between employer and employed has hitherto, generally speaking, been based on false and glaringly unscientific principles. Trades unions and employers' federations exist more for organised defence and resistance than for peaceful progress, and it lies in the very nature of the present system of industrial management that this should be so. There is really as little cause for the two elements involved in industry, namely, capital and labour, to be divided, as for a household to be divided against itself. Employers and employed live, as it were, under one roof and for one purpose, the one being absolutely dependent on the other. They must rise, continue, or fall together. For want of a thorough understanding of this economic law, as old as the hills, yet never universally recognised, the path of industrial development has been strewn with the wreckage of lives, the waste of capital and energy, and at times with incalculable misery for thousands of women and children comparable only to a state of active warfare.

Where there is no true vision the people perish. Without the desire to learn, to know, to see and trust to a better way than that of recurring strife, the people deserve to perish. We must have visions in relation to industrial peace such as we visionaries hold in relation to international peace. After this Armageddon has been fought out and the victory won by those who fight for truth, justice, and right, against what appears to be the frantic force of evil doers, we must resolve to start again on a higher plane of industrial relationship, in the attainment of which education on the lines already indicated must necessarily be the leading factor.

No country in this world can so easily change the moral and mental growth of its children from the wrong direction to the right as Great Britain can. We possess absolute political freedom, the poorest of the poor amongst us casting as potent a vote under our self-governing constitution as the richest magnate in the land. With the political freedom and individual responsibility such as we enjoy, perfect discipline must ensue if we become educated scientifically to do the necessary thing in the right way, for the welfare of the country and of all who dwell therein.

If liberty and self-government by the people for the

people do not yield this result, it is obvious that we are not efficiently educated, that is, we are either not intelligent enough to know the right way from the wrong, or, knowing it, we do not care to follow it; which means that our moral nature, or higher self of spirit and conscience, has not become educated equally with our intellectual abilities.

The one outstanding menace, which imperils our very existence as an industrial nation, is the chronic separation of capital and labour, employers and employed, into opposing camps. Until the necessity of perfect unity of interest, of motive, and of purpose is recognised and established, we are building our industrial edifice on the sand, liable at a moment's notice to be shattered by the winds and storms of passionate discontent which sweep away what the best culture and skill may have erected. It is eminently unscientific to build on sand when rock is at hand. In building up our industries scientifically let us not forget that in its broadest sense science, as has been well said, "includes the elements of the theory of morals and those of political and social life." There is a science, therefore, which if applied to the elements of capital and labour will blend them into one organic, harmonious whole. The science of education will teach both labour and capital to look at the problems of industrial growth and success with cultured minds, instead of as now with minds only half made up—prone to err, to misjudge men and things, unable to see with an instructed sense of proportion, to differentiate between that which is true and that which is false, between right and wrong, in the complex questions affecting both. The science of management is as important as the science of mechanics. The latter shows the laws of right construction; the former, the way to peaceful control, to unity of purpose, and, above all, to equity in sharing results of the organic whole of capital and labour.

SMITHSONIAN EXPLORATIONS.

A FULLY-ILLUSTRATED pamphlet containing brief accounts of the more important explorations and field-work undertaken during 1914 by members of the staff of the Smithsonian Institution proper and of its branches, the National Museum, the Bureau of American Ethnology, and the Astrophysical Observatory, has recently been issued.

Dr. C. D. Walcott briefly outlines his summer's work in British Columbia and Montana, in continuation of his previous geological explorations in those regions. In the lower portion of Deep Creek Canyon, south-east of the city of Helena, a deposit of siliceous shale was examined, where some years ago Dr. Walcott discovered the remains of crab-like animals suggesting in form the fresh-water cray-fishes found in streams and ponds all over the world. "These fossils," says Dr. Walcott, "are the oldest animal remains now known, and the algal deposits, which occur at intervals for several thousand feet below the shales containing the crustaceans, are the oldest authentic vegetable remains. It is also most interesting that two types of bacteria have been found in a fossil state in the rock in association with the algal remains."

Continuing the excavations at the cave deposit near Cumberland, Maryland, Mr. J. W. Gidley, of the U.S. National Museum, has added to the already important collection from this region more than 400 specimens of fossil animals, deposited there in Pleistocene time. Among these was a practically complete skeleton of the large extinct peccary, measuring more than 4 ft. in length, a partial skull of a wolverine, and several skulls of extinct species of the black bear.

Mr. H. C. Raven, who has been collecting animals and birds for the Smithsonian Institution through the generosity of Mr. W. L. Abbott, gives interesting information respecting the inhabitants and the animals of Celebes, Malay Archipelago. Mammal life, according to Mr. Raven, is not nearly so plentiful in Celebes as in Borneo, where he was collecting during the previous season, but several peculiar animals have been captured by him, among them a specimen of Babirussa, a pig with peculiar erect tusks curved backward above the forehead.

An expedition under the joint auspices of the Smithsonian Institution and the Cuban Government spent two months on the coast of western Cuba for the purpose of making a complete biological survey of the waters of that region, and incidentally to obtain specimens for the exhibition series of the National Museum. The Smithsonian was represented by Mr. John B. Henderson, a Regent of the Institution, and Dr. Paul Bartsch, of the National Museum. Extensive dredging operations for securing marine specimens were carried on daily, and from several shore stations large numbers of specimens of land forms were taken. The expedition was quite successful, and a great quantity of valuable material is now in the hands of specialists of the National Museum for final report. Particularly good were the collections of marine organisms, especially the molluscs.

Early this year arrangements were made whereby Mr. Neil M. Judd, of the National Museum, was enabled to accept an invitation to participate in the archæological investigations in Guatemala, conducted by the American School of Archæology. Mr. Judd's special work was to superintend the making of plaster casts of several of the huge stone monuments that have made world-famous the ruins of the so-called "Temple Court," the religious centre of the sacred city of Quirigua. After this work, Mr. Judd paid a brief visit to the Mexican border to ascertain the anthropological possibilities among the Indian tribes of this region. But little survives, in the remnants of the Quiche, Cachiquel, and Tzutuhil tribes, to indicate the strength and magnificence of the Quiche empire which Pedro de Alvarado destroyed in 1523, at the beginning of his conquest of Guatemala. Although the natives of these interior valleys have always been considered treacherous, Mr. Judd experienced few difficulties, and his hurried journey seems to indicate that extended anthropological investigations in this region will be as easy as they are desirable.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Sir W. H. Solomon and Prof. G. H. Bryan have been elected to honorary fellowships at Peterhouse.

LEEDS.—The Senate, at a meeting held on November 3, passed a resolution expressing deep regret at the death of Sir Arthur Rücker. The Senate places on record its sense of obligation to Sir Arthur Rücker, who, with his colleagues forming the first staff of the Yorkshire College of Science, laid the foundations of its intellectual work and corporate life. It was their advice which encouraged the council of the Yorkshire College of Science so to widen the scope of its studies as to enable it to develop into a University embracing the disciplines of arts, science, medicine, and technology. Furthermore, the Senate records its grateful appreciation of the part which, in his last

years, Sir Arthur Rücker (as a member of the Advisory Committee on University Grants) took in framing the federated superannuation system for universities, now successfully adopted by all the university institutions of modern foundation in England and Wales.

OXFORD.—Dr. E. W. A. Walker, fellow of University College, has been appointed lecturer in pathology for five years from January 1, 1916.

Prof. H. L. Bowman, Waynflete professor of mineralogy, reports two valuable benefactions to his department. (1) Under the will of the late Sir Arthur Church has been bequeathed 100*l.* for the purchase of apparatus and specimens, together with the chemical and mineralogical apparatus and instruments in Sir Arthur's laboratory and his collection of mineral specimens (other than cut gem-stones). (2) A valuable collection of minerals made by the late Dr. Hugo Müller, containing some 2000 good specimens, has been presented by Mrs. Müller.

MR. A. R. HINKS, the Gresham lecturer on astronomy, will deliver four lectures on "Navigation and Maps" at Gresham College, Basinghall Street, E.C., on November 16, 17, 18, and 19. The time of the lectures is 6 p.m., and the admission is free.

IT is announced in the issue of *Science* for October 29 that the sum of about 80,000*l.* has been subscribed in the University of Michigan alumni campaign for 200,000*l.* with which to build and endow a home for the Michigan Union, as a memorial to Dr. James B. Angell, president emeritus; and that Delaware College, at Newark, has received a gift of 100,000*l.*, from a donor whose name is withheld, for the construction and maintenance of buildings.

THE Comité des Visites aux Blessés Belges has collected about three thousand volumes of French and Flemish works in order to provide Belgian wounded soldiers with literature in their own language. The committee now informs us that amongst the wounded there are many students and technical workmen who desire to follow up their studies, and for this purpose want books on science and engineering, chemistry, physical science, mathematics, mechanics, electricity, and other sciences; also commercial study books, technological works, etc. Any of our readers possessing surplus volumes of this nature should address them to Madame Carton de Wiart, at the library department of the committee, Sardinia House, Sardinia Street, Kingsway, London.

WE hope the appeal of the eminent physicians and surgeons on behalf of the London (Royal Free Hospital) School of Medicine for Women will meet with a generous and immediate response. For the enlargement of the school premises 30,000*l.* is required, and already 18,000*l.* has been received. This school (the only one in London at which women can receive a medical education) was rebuilt in 1900 in the expectation of an average annual entry of thirty-five students. During the last six years the annual entry has risen to sixty students. This session 110 new students have entered the school. Enlargement of the laboratories and lecture-rooms has become urgently necessary, and, an adjoining site having been secured, building has already begun. Already there is a grave shortage of men medical students, and in view of the valuable medical work women have done during the last forty years, it is earnestly to be hoped that women medical students will receive all the encouragement and help it is possible to provide.

THE calendar of the twenty-fourth session, that for 1915–16, of the University College, Reading, has been received. Notice is given in it that while the college will make every effort to adhere to the arrangements announced in the calendar, it may be necessary to modify them owing to the exceptional circumstances brought about by the war. The teaching work of the college is organised in three faculties—letters, science, and agriculture and horticulture, and in three departments—fine arts, music, and commerce and technical subjects. The faculty of agriculture and horticulture dates from 1913, and grew out of a department of agriculture formed in 1893. As a result of the Development Act of 1909, England has been divided into ten agricultural provinces, each consisting of a group of neighbouring counties and centred on a University Agricultural Department or an Agricultural College. The province which is centred upon University College, Reading, consists of the following counties:—Berkshire, Buckinghamshire, Dorset, Hampshire, the Isle of Wight, Middlesex, and Oxfordshire. It is the desire of University College, Reading, to assist in every possible way agriculturists who are resident in the Reading province, and, in cases where the county council contributes to the funds of the college, reductions are made in the fees charged to residents in those counties. As the result of an agreement with the British Dairy Farmers' Association, the British Dairy Institute was moved from Aylesbury to Reading in 1896. It is under the control of a joint committee of representatives of the association and of the college.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, November 4.—Sir William Crookes, president, in the chair.—Prof. W. E. **Dalby**: A diagram to facilitate the study of external ballistics. The paper describes a semigraphical method for solving problems relating to motion in a resisting medium, with particular application to the motion of a projectile after it has left the gun. It is shown how easily and rapidly problems of direct fire can be solved by the aid of the diagram, with an accuracy sufficient for most practical purposes, and probably to the same order of accuracy as that of the data from which the primitive curve is derived. For a given muzzle velocity, the range, the time of flight, the angle of elevation corresponding to the range, the angle of descent, found from the diagram, are respectively multiplied by the ballistic coefficient to get the actual values of these quantities. It is shown how easily Siacci's function can be integrated, and a curve showing the integral value of the function is added to the diagram. The diagram may be used for the solution of problems relating to high-angle fire just in the same way as the ballistic tables are used. The actual velocities are replaced by pseudo-velocities calculated in the way explained in the gunnery text-books, and then these pseudo-velocities are used with the diagram.—W. B. **Hardy**: An application of the principle of dynamical similitude to molecular physics. The principle of dynamical similitude is developed and applied to the case of the internal latent heat of evaporation. It is found that if temperature be proportional to the mean energy of progressive motion of the molecules, the internal latent heats of dynamically corresponding states should be given by the equation $LM = a\tau$, where L is the latent heat, M the gram-molecular weight, a a constant, and τ the temperature. This equation may be used either to identify corresponding temperatures or to test some assumption as to corresponding temperatures.—R. **Jones**: The motion of a stream of finite depth past a body. The method of considering the two-dimensional flow of an infinite fluid past a

body, as being constituted of a potential motion plus a circulation, is in the present paper applied to a stream of finite depth.—K. **Terazawa**: Deep-sea water waves caused by a local disturbance on or beneath the surface. Analytical investigations of sea-water waves produced by a local disturbance on the surface have been made by various writers. Prof. H. Lamb's paper (Proc. Lond. Math. Soc., (2) II., p. 371, 1904), on the subject is the most concise and comprehensive. The earlier part of this paper consists of an extension of his investigations, and discusses the cases where the initial prescribed displacement of the surface or impulse applied to it is of the form $A \cos m\theta/\varpi$, where ϖ is distance from origin, instead of being condensed in a point. The displacement of the surface is expressed as a power series of gt^2/ϖ, with zonal or associated harmonic functions as its coefficients. As to the sequence of events at the centre of the initial disturbance, there has hitherto been little examination. In this paper that point is discussed, the initial disturbance being assumed to be of the form $A/\sqrt{(b^2+\varpi^2)}$, and it is found that for this type there occur only a few rises and falls of the surface which cease in a short time. The latter part of the paper is devoted to the problem of the tidal wave caused in deep water by a submarine explosion having its source situated at a point or along a horizontal line, assuming this source to be placed so deep, or its force to be so gentle, that the surface of the water is not broken by the ejection of a water-column.—W. G. **Duffield**: The consumption of carbon in the electric arc. Experiments have been carried out to determine the amount of material lost by the poles of a direct-current carbon arc under different conditions of current and arc length. Before beginning the weighings the arc was burnt to shape; on this account consistent results have been obtained. For a given current the carbon consumption of both the anode and the kathode increases with the arc length until a constant value is reached. Using long arcs the consumption per coulomb decreases with increasing current; the ratio of anode to kathode consumption is about 1·5, increasing slightly with the current. The study of extremely short arcs leads to the following conclusions:—(1) The loss of an atom of carbon from the kathode of a very short carbon arc is accompanied by the transfer between the poles of a quantity of electricity equivalent to four electronic charges. (2) In long arcs the loss is due to this essential carbon disappearance plus a quantity due to combustion. No. (1) has been found to hold over a range of current strengths from 2 to 100 amperes.—Hon. R. J. **Strutt**: Observations on the fluorescence and resonance of sodium vapour. II.—J. G. **Leathem**: Some applications of conformal transformation to problems in hydrodynamics. Supplementary note.—L. **Isserlis**: The conditions under which the "probable errors" of frequency distributions have a real significance.—Prof. W. M. **Thornton**: The reaction between gas and pole in the electrical ignition of gaseous mixtures.—Lieut.-Col. A. G. **Hadcock**: The longitudinal strength of cylinders closed by screw plugs.—J. G. **Leathem**: Some applications of conformal transformation to problems in hydrodynamics.—A. B. **Wood**: Volatilisation of extremely thin radio-active deposits.—S. W. **Richardson**: Some experiments on the properties of dielectrics.—W. B. **Bottomley**: a bacterial test for plant-food accessories (*Auximones*).

Challenger Society, October 27.—Dr. E. J. Allen in the chair.—L. A. **Borradaile**: The mandibles and associated structures in prawns. The structures which surround the mouth of the common prawn were described, suggestions were made as to their functions, and problems presented by their morphology were discussed. Reasons were given for believing some at least of the appendages to be derived from limbs of a type which possessed four endites proximal to the endopodite, and one in the region of the ischiopodite. The rest of the endopodite might represent a sixth endite, such as that found on the thoracic limbs of Apus.

PARIS.

Academy of Sciences, November 2.—M. Ed. Perrier in the chair.—The President announced the death of Dr. C. J. Bouchard, member of the academy.—G. **Bigourdan**: The astronomical work of Fabri de Peiresc. An account of work done between 1604 and 1636.—Paul **Vuillemin**: The stamens in the Tropeolaceæ. The view put forward is the typical arrangement comprising three episepal stamens and six epipetal stamens. These do not form a cycle distinct from the corolla. The total number is reduced to eight in the normal flower, because the sixth epipetal stamen and the third episepal stamen form one.—J. **Haag**: The method of Otto.—P. **Zeeman**: Fizeau's experiments for different colours of the spectrum. If c is the velocity of liquid in a vacuum, n the refractive index of the fluid in motion, and v the velocity of the fluid relatively to the observer, Fresnel's formula for the resulting velocity is $v/n \pm (1-1/n^2)v$. Lorentz proposed to replace the coefficient of displacement,

$$(1-1/n^2), \text{ by } 1-1/n^2-\lambda/n.dn/d\lambda,$$

and the experiments described in the present paper were designed to compare these two coefficients. The arrangement due to Michelson and Morley (1889), slightly modified, was employed, and measurements were carried out with monochromatic light, in which λ varied from 4500 to 6870 Angström units. The experimental figures were in close accord with those calculated from the Lorentz formula,

$$1-1/n^2-\lambda/n.dn/d\lambda.$$

Full details are reserved for a later communication.—Marin **Molliard**: The experimental production of tubercles at the expense of the main stem in the potato. M. **Fleury**: The morphology of the massif of Porto-de-Moz (Portugal).—M. **Bergonié**: The electrical power absorbed by the electro-vibrator. The best conditions of use of this apparatus.—Louis **Roule**: The migrations of fishes of the family Mugilideæ.

SCIENCE FOR ALL.

THE little attention given to science in education and in the public mind has been the theme of many essays and addresses. In both cases science is usually regarded as suitable for study by a select few only, and not as an essential part of all modern life and thought. Latin and Greek, history, and the literature of other times receive almost as much consideration now as they did before scientific discovery changed the whole aspect and outlook of life; and the mass of the people, as well as most of their leaders, are in their training deprived of light which should illumine the minds of all.

We do not for a moment suggest that the end of all education should be preparation for scientific careers; neither do we ask that men of letters, statesmen, and administrative officers of departments of State should all be scientific experts. To make such claims would be unreasonable, though not more so than the accepted principle that familiarity with classical languages and literatures is a necessary qualification for such positions, and that the first place must be given to these subjects even if matters more closely related to modern conditions of existence in war or in peace have to be neglected. Our claim is that everyone—from elementary-school pupil to college don—should be made acquainted with appropriate outlines of scientific work and thought. We want science to be a part of every general education, and we urge that the times demand this recognition of its influence and potentialities. When this modernisation has been accomplished, facilities for scientific work will be increased a hundredfold, and the public will not be deceived by sensational announcements in the daily Press, or tolerate official indifference to the growth of natural knowledge.

It may be doubted whether the methods now followed in the teaching of scientific subjects in schools are as effective in creating or fostering interest in science as those formerly adopted. Twenty years ago or so, much more attention was given to the attractive side of science than is now the case. Pupils were shown interesting experiments or were encouraged to read about remarkable facts and phenomena in Nature; and if they took a practical course they were able to cover a fairly wide field. In physics, for example, a student could learn something about the whole elementary range—mechanics, heat, sound, light, electricity, and magnetism; in chemistry he would see many striking changes and effects, such as impress themselves upon the youthful mind; in natural science he would be told many wonderful facts about birds and beasts and other objects—animate and inanimate—in the world of Nature.

No comprehensive survey of this kind is possible under existing conditions of science teaching in schools. In physics few students get beyond a course of work in mechanics and heat, and they leave school without receiving any instruction in other branches of the subject; their practical chemistry is frequently limited to manipulations and a study of air and water; and work in Nature-study means mainly the observation of a few facts of plant physiology or of animal development and habits.

Personal observation, intelligent inquiry, quantitative test, are, of course, essential factors of scientific method, but we believe that to insist upon all school science being controlled by them is a mistake. The limited amount of time that is given to science in schools renders true research methods impracticable; and pupils in general can scarcely be expected themselves to possess the motive and the purpose that lead to scientific investigation. Every teacher knows that only rarely is a pupil capable of initiating an experiment or of arriving at a statement of law or principle from results obtained by practical work. Little justification can be found, therefore, for the concentrated attention given to a few subjects, with the view of imparting knowledge of experimental methods, when such a course means that the wonders of the fields beyond are kept outside the range of vision.

School science as at present taught, and as defined by examination syllabuses, seems to proceed on the assumption that every pupil is to become a skilful experimenter, or an original investigator, in the realms of Nature. Courses of laboratory work designed with this intention may not unfairly be compared with the test-tubing of former times, which aimed at making every boy an analytical chemist. The practical work now done is certainly more valuable as a means of scientific training than it used to be, but it may be doubted whether by such exercises science can claim a prominent place in the curriculum. Modern life requires that the elements of scientific method and knowledge should form part of every educational course. School work should not be concerned in training experts in science, any more than specialists in classics, but with imparting the rudiments of a liberal education to all pupils, so as to awaken

interest which will continue when schooldays are over.

That is the standard—abiding interest—by which successful teaching may be judged; and we are disposed to think that the descriptive and qualitative school science of a generation or two ago was better adapted to promote such continued attention than is the quantitative work in the narrow fields mapped out for instruction to-day. In their anxiety to impress pupils with a sense of scientific accuracy and cautious conclusion, advocates of the methods now in vogue have forgotten that it is even more important to present a view of science which shall be human as well as precise. To the general neglect of this aspect of scientific study, which appeals to all, must be ascribed the fact that science has lost much of its former popularity, and has become a task in which only a favoured few can hope to excel.

It is a thousand pities that science should be considered to be merely a burden of material fact and precise principle which needs a special type of mind to bear it. We want much more of the spirit, and less of the valley of dry bones, if science is to be made of living interest, either during school life or afterwards. We want everyone to know something of the lives and work of such men as Galileo and Newton, Pasteur and Lister, Darwin and Mendel, and many other pioneers of science. The way to inspire wide interest in the achievements of men like these is not by the laboratory teaching of a few, but by suitable descriptive literature for all. In books intended for general reading, information should be made subordinate to inspiration, and broad outlines of great discoveries or fruitful ideas should be presented instead of tedious detail. It should be shown that self-sacrifice, persistence, courage, duty, accuracy, love of truth, and like attributes of greatness, may all be abundantly exemplified from the careers of men of science.

The achievements of science represent increase of knowledge, not alone for the man who makes it, not alone also for the nation or country to which he belongs, but for the whole human race. The conquests of science do not mean the aggrandisement of one country or people at the expense of another, but gifts to all who will receive them. The only domain which it is desired to penetrate is that of ignorance; and the fight is against the physical and mental death which is its heritage. Ignorance made plague the terror of Europe in the Middle Ages; science has proved that the disease is due to a bacillus which is conveyed by fleas from rat to rat, and from rats suffering from the disease to mankind. Ignorance ascribed malaria to a miasma or bad air arising from marshy places; science has shown it to be carried from one human being to another by a certain species of mosquito. Ignorance of the cause of yellow fever made the regions around the Caribbean Sea the White Man's Grave, where the risk of death for the visitor was greater than in a battle; knowledge that the disease is communicated from an infected to a healthy person by the bite of a particular mosquito has been the means of converting the same places into tropical health resorts. One practical result of the discovery of the cause of yellow fever was that it made possible the construction of the Panama Canal. It was not a hostile army or political difficulties that obstructed the work commenced by de Lesseps, not mountain chain or desert waste, but an insect which raised a barrier of disease and death between endeavour and accomplishment.

We have in uplifting stories of this kind—and there are many others—plenty of themes for epics which, rightly used, will stimulate interest in science, in both old and young. When a place for such literature is found in every educational course, the number of people who will follow scientific work with sympathetic minds will be greatly increased. At present school science means mostly determinations of specific heats or chemical equivalents, and similar exercises, while the deeds and thoughts which give living interest to material studies are neglected altogether. We do not ask that science students only should be given much broader views of natural knowledge than can be acquired through laboratory manuals and class text-books, but that the historical and literary studies in all schools and colleges should include works in which great scientific achievements and generalisations are expounded. We are confident that such subjects can be made attractive to almost every mind, and that the want of general and intelligent interest in them is due largely to the neglect of descriptive scientific literature in all stages of instruction.

It is unfortunately true that men of science themselves are often interested only in their own special field of work, and pay little attention to what is being done in other directions. These are the days of specialised study, and though the high powers used for the eyepieces enable new details to be discerned, the field of view is greatly restricted in extent, and the sense of true proportion is lost. Specialisation is essential for advance, but when it also means indifference to external movements and influences, it does not repre-

sent the highest type of intellectual activity. We cannot urge with any force the desirability of bringing the laity to appreciate the outstanding points of scientific work if specialists in particular sections of such work manifest no interest in the results of investigations by their colleagues in other departments, or will not trouble to make themselves understood outside their own esoteric circle. Papers read before scientific societies are now so highly specialised that only occasionally can they be followed with intelligent interest by the whole of the fellows present at a meeting, and usually not more than two or three people are capable of criticising them. As this is the case in circles where at any rate the general language of science is understood, it is not strange that people who have not had a scientific education should believe that scientific description must be beyond their comprehension.

This belief is probably responsible for the fact that there is little demand for popular works on science and few large audiences for scientific lecturers. We can say without fear of substantial contradiction that in such an inspiring subject, for example, as astronomy, attempts at popularisation by books or lectures have less chance of success than they had fifty or a hundred years ago. We are well aware that there are a few individual exceptions to this generalisation, but the statement can be fully justified as a whole, not only as regards astronomy, but also by the experiences of most authors and lecturers in other branches of science. There has been a vast increase in periodical publications and general literature, but the increase in scientific literature has been in the direction of text-books and treatises rather than in popular works, to which little encouragement is given, either by men of science or the public.

We should be sorry to suggest that scientific work is necessarily associated with poor literary style; indeed, we are sure that the literary compositions of men of science compare very favourably with those of other workers who are not purely men of letters. It may be doubted, however, whether sufficient encouragement is given to young scientific men to cultivate the power of clear expression, or whether sufficient appreciation is shown of efforts at making science intelligible to the people. An author like Mr. H. G. Wells, who creates wide interest in scientific work, is doing far better service to science than he would if he had concentrated his attention upon the minute biological structures of his early days as student and teacher. It would be greatly to the advantage of science if there were many more writers possessing like scientific knowledge with brilliant imagination and convincing pen.

Science can only secure its rightful position in a democratic State when its work and worth are widely known and understood. The makers of new knowledge can be trusted to continue to add to the stores already accumulated, but they should remember also that popular interest means increased support for their work and greater use of the results. It is rarely that great capacity for original investigation is combined with the gift of attractive exposition, and more rare to find both qualities being used for the popularisation of science, as, for example, in Sir Ray Lankester's series of masterly notes and essays, three volumes of which have now been published. We believe the influence of such literary work upon the public mind is much greater than is generally understood, and we should like to see many equally attractive efforts of a similar kind in other scientific fields than those with which Sir Ray Lankester is most intimately acquainted.

The war has made people think of more serious things than those which had their attention a year or two ago, and there are signs that a more satisfying literature will be required than the light pabulum which has hitherto served. What could be better adapted to provide for the coming need than the rich materials of science when attractively displayed? It is the privilege of scientific workers to have garnered these stores; and it is equally their duty to see that the nation does not perish for want of the stimulating food which they can furnish. If science does not come into its kingdom in the immediate future, it should not be for want of endeavour to enlighten the mind of the public and create intellectual interest in its aims, but because the people are content to be ignorant of the truths learned in the innermost courts of the temple of Nature, and to be without the power which such knowledge can give them.

ORIGIN OF THE INDIAN CASTE SYSTEM.

The People of India. By Sir H. Risley. Second edition, edited by W. Crooke. Pp. xxxii + 472 + xxxv plates. (Calcutta and Simla: Thacker, Spink and Co.; London: W. Thacker and Co., 1915.) Price 21*s.* net.

THIS memorial edition of the late Sir H. Risley's standard work on Indian anthropology has fortunately been entrusted to the competent hands of Mr. W. Crooke. As no notes were left by the author for a new edition, the editor has reproduced the text generally as it stood in the first, which had quickly run out of

print; but Mr. Crooke has introduced many improvements. He has brought the statistics up to date, secured greater uniformity in spelling the vernacular names, added numerous footnotes, correcting statements and theories which have been proved to be erroneous or doubtful, and given an appreciative memoir of the author's pioneer anthropological work in India.

Important additions also have been made to the illustrations, which previously had been restricted to rather inferior reproductions of several of the beautiful photographs by Sir B. Simpson in Dalton's "Descriptive Ethnology of Bengal"—a work also now difficult to procure. The inclusion of some excellent photographs for other parts of India makes the series now more representative.

The main thesis of the book is the contentious one on the origin of the caste-system. There is no doubt that Risley exaggerated the antiquity of the present social grouping of the people in his belief that the supposed fixity of caste dated to a remotely early period, and had thus presumably preserved in India a remarkable purity in physical type. Mr. Crooke, however, shows that caste in its modern rigid form in India is relatively recent. The older custom, as seen in the Vedas and Epics, recognised the possibility of a member of the "warrior" class (*Kshatriya*) becoming a Brahman, or *vice versâ*. A second wife could be taken from any lower class, and such laxities in practice still prevail in the more outlying districts of the Himalayas and the Panjab amongst groups of relatively pure Aryan stock. In many areas in India it is shown that the existing tribes and castes represent mixtures of various races which had amalgamated within a comparatively late historic period.

On the disputed origin of the warlike castes of Upper India, the long-headed Rajputs, Jats, and others, Risley opposed the present fashionable theory which would bring these people from Central Asia. This he did on the old idea that the people of Central Asia were of a uniform brachycephalic type, which is now known to be certainly not the case. Mr. Crooke seems to approve the recent theory of Smith and others that the Gurjari and the other associated "Rajput" tribes of Upper India are largely, if not wholly, formed by the Hun invaders of the early centuries of the Christian era. Yet it is precisely in these and associated tribes that Risley finds his purest Aryan type!

Regarding the Marathas, the dominant tribe of Western India, Risley's suggestion, based upon some reputed, but not clearly established, brachycephalism in the Deccan, is that they originated in bodies of Scythians driven down from the Western Panjab and intermarrying with the Dravidians. Mr. Crooke points out that there is no historical nor even traditional evidence of any Scythian migration into the Deccan; whereas the Marathas are closely connected with a mixed race of cultivators extending over a wide area, from the Deccan to the Ganges Valley, and known as Kumbi or Kurmi. These and other results of later research would no doubt have been considered by the author himself had he lived.

To many workers the most important part of the book will perhaps be the anthropometric tables, consisting of seriations of the several physical types. These and the maps of caste-distribution are of permanent value. The large collection of caste-proverbs will be found curious and interesting to students of folk-lore.

The only mistake we have noticed in the references is that the article cited at page 2 from the "Journal, Royal Asiatic Society" should be for the year 1898, and not 1908.

L. A. WADDELL.

PHILOSOPHY OF SCIENCE.

(1) *Proceedings of the Aristotelian Society.* New series, vol. xv., containing the papers read before the Society during the Thirty-sixth Session, 1914–1915. Pp. 441. (London: Williams and Norgate, 1915.) Price 10*s.* 6*d.* net.

(2) *Selections from the Scottish Philosophy of Common Sense.* Edited by G. A. Johnston. Pp. vii+267. (Chicago and London: The Open Court Co., 1915.) Price 3*s.* 6*d.* net.

(1) OF the twelve papers and symposia collected in the Proceedings of the Aristotelian Society for the last session, four are direct criticisms of positions taken up by Mr. Bertrand Russell. In the inaugural address on "Science and Philosophy," Dr. Bosanquet criticises the view, maintained in Mr. Russell's recent Lowell Lectures, that philosophy, as the science which aims at stating all that can be known *a priori* about all possible worlds, should be ethically neutral, and that it is just because philosophy in the past has been biased by the desire for agreeable conclusions that philosophy has not made the same progress as the physical sciences. Dr. Bosanquet holds that this view implies an antecedent limitation of philosophy, and involves the confusion that because the interest of philosophy is purely theoretical, therefore its subject-matter is itself theory and its objects.

In a paper of extraordinary acuteness, Mr. C. D. Broad deals with Mr. Russell's attempt in

the same lectures to work out a phenomenalist philosophy of science. All physical science starts with directly observable sense-data, and physical laws can only be verified by finding that predictions as to the nature of sense-data based on these laws are actually borne out by direct observation. Accordingly Russell argues that it is theoretically possible, on the principle of Ockham's razor, to state all that is implied by the laws of physics in terms of sense-data alone.

Mr. Broad urges (*a*) that Russell's attempt at phenomenalism is not nearly so "economical" as he supposes. Whereas the ordinary view assumes imperceptible physical objects, the qualities and existence of which are inferred from sense-data, Russell gives us an immensely greater number of imperceptible sense-data, likewise inferred from the sense-data of which we are immediately aware, which are of the same logical kind as physical objects on the ordinary view. The difference in simplicity is not, then, in Russell's favour. (*b*) Russell's theory is very far from expressing the laws of physics in terms of sense-data. *E.g.*, take the statement that iron expands when heated. It is not enough to say that if a certain group of grey visual sense-data is accompanied by a certain group of hot tactual sense-data, then as the latter get hotter the former get larger. Usually the increase in length can only be detected by a micrometer gauge. But the micrometer must in turn be analysed into visual and tactual sense-data, and further the facts which on the ordinary physical theory we call the proper use of the micrometer must also be resolved into muscular and other sense-data. Exact statement of a physical law in purely phenomenal terms is, therefore, intolerably complicated. What physical science and common sense do is to analyse such complicated but directly verifiable statements into two laws more general but not separately verifiable, one as to changes outside the body, "Iron expands when heated," and the other stating the action of external objects upon the body which results in the awareness of sense-data and of changes in them.

In a paper entitled "Complexity and Synthesis" Mrs. Adrian Stephen compares the views of Russell and Bergson as to the nature of sense-data. Prof. Stout's paper, "Mr. Russell's Theory of Judgment," is a criticism of the treatment of judgment in Russell's "Problems of Philosophy." Russell there maintains that the fact of error forces us to the conclusion that judgment is not a dual, but a multiple relation, *i.e.*, one which, like "between," involves more than two terms. Othello's judgment that Desdemona loves Cassio is not a relation joining Othello's mind to the one objective complex, Desdemona's love of Cassio, because the falsity of Othello's judgment means that there is no such thing as this complex: the belief unites Othello's mind and the three objects Desdemona and loving and Cassio. Stout urges that on this view there is nothing before the mind to correspond to actual fact. The mind in judgment cannot be aware of the judgment complex, because that complex includes the act of judgment. And the objects of judgment have, apart from the relation of judgment, no order which can be compared with the factual order which is to determine their truth or falsity.

In his paper, "Conflicting Social Obligations," Mr. G. D. H. Cole attempts to provide a philosophical basis for the social and economic doctrine he has put forward in his recent works, "The World of Labour" and "Labour in War Time," and in a number of articles in the *New Age* and the *Herald*. Mr. Cole's object is to restate Rousseau's doctrine of the general will in such a way as to leave room for many other associations, industrial and religious, as well as the State. Mr. Cole's demand is for functional devolution of power for such associations, "a demand that the State itself should be regarded only as an association—elder brother, if you will, but certainly in no sense father of the rest." And if the individual finds himself torn between loyalty to the State and loyalty to the industrial body to which he belongs, we can only say, with Rousseau, that he ought to consider the good of the community as a whole.

Messrs. McDougall, Shand, and Stout write on "Instinct and Emotion"; Prof. Lloyd Morgan on Berkeley's doctrine of *esse*; Mr. A. Cock on the "Æsthetic" of Croce; Dr. Tudor Jones on the philosophy of values; Prof. A. Robinson on the philosophy of Maine de Biran; Dr. Aveling on "Some Theories of Knowledge" (his treatment is largely based on the recent work of Father Leslie J. Walker); and Miss E. E. Constance Jones and Messrs. Bosanquet and Schiller on "The Import of Propositions."

(2) Mr. G. A. Johnston has earned the gratitude of students of philosophy for collecting within a small compass the more characteristic passages from the works of Reid, Ferguson, Beattie, and Dugald Stewart. At a time when many are inclined to distrust the Kantian solution of Hume's sceptical difficulties it is interesting to read an alternative solution of these difficulties in the natural realism of the Scottish Philosophy of Common Sense. In a brief introduction Mr. Johnston gives an account of the relation of Reid and his followers to Locke, Berkeley, and Hume.

E. H. STRANGE.

DIRICHLET SERIES.

The General Theory of Dirichlet Series. By G. H. Hardy and Marcel Riesz. Pp. x+78. (Cambridge: At the University Press, 1915.) Price 3s. 6d. net.

IT is well known that Dirichlet made a new start in the theory of numbers by bringing it into connection with certain analytical functions of the form $\sum_h n_h^{-s}$, n_h being an integer, and s a real quantity. In the present tract the definition of a Dirichlet series is

$$f(s)=\sum_1^\infty a_n \exp(-\lambda_n s),$$

where (λ_n) is a sequence of real increasing numbers converging to $+\infty$, and s is a complex variable. This obviously includes Dirichlet's functions, and also those considered by Dedekind, Riemann, Landau, and others, in the same connection.

In the earlier chapters we have a summary of the known elementary properties of $f(s)$, such as the conditions of its convergence when regarded as a sum in the ordinary sense, and so on. But the most novel, and principal, part, due mainly to Dr. Riesz, is concerned with what he calls the summability (λ, κ) of $f(s)$. It is important that the meaning of this should be properly understood. Let s_n mean the sum of the first n terms of $f(s)$; then Dr. Riesz associates with this a function which we may call $\sigma_n(\lambda, \kappa)$, where κ is an arbitrary positive number, and λ is a functional symbol defined by $f(s)$ and κ, so that we have a sequence $[\sigma_n(\lambda, \kappa)]$ which we may consider as depending upon κ. If this new sequence has a limit L, we say that $f(s)$ is summable (λ, κ). In the definition we only consider the *formal* nature of $f(s)$, so that it does not matter whether $f(s)$, regarded as a series in the ordinary way, is convergent or not. Thus we have a sort of extension of the theories of Poincaré, Borel, etc., about divergent series.

The conditions that L may exist give properties of $f(s)$ considered as a formal expression, and hence certain conclusions of an arithmetical nature can be drawn. It is in the further development of these deductions that we may hope for further information of interest. The mere fact that from a sequence (s_n) we may be able to construct a sequence (σ_n) which agrees, in the limit, with (s_n) when the latter is convergent, and may be called its "sum" when it becomes divergent in the ordinary sense, is a barren definition until we apply it to something concrete; if we can do this, it may be a very valuable resource, as in the case of asymptotic summation. Everything goes to show that the + we use in writing infinite series is in some ways less appropriate than the comma of the old-fashioned "progressions"; it will not matter if we remember what we are doing, and that there is no such thing as the actual sum of an infinite number of terms.

One observation in this tract is liable to misunderstanding. It may be true that Cahen is the first to discuss $f(s)$ *systematically* as a function of a complex variable s; but the first step in this direction was taken by Riemann in his famous paper on the distribution of primes. To arithmeticians, at any rate, it is the development of Riemann's results that is of principal interest at present; other problems of the same kind naturally present themselves, as, for example, the frequency of cases where p and $(p+2)$ are both primes, like (5, 7) or (11, 13). The new analysis may throw some light on these and other dark places. In any case, this tract will be welcome for its concise statement of known facts, and its bibliography, which supplements that of Landau.

G. B. M.

OUR BOOKSHELF.

Fungoid Diseases of Farm and Garden Crops. By Dr. T. Milburn. Pp. xi+118. (London: Longmans, Green and Co., Ltd., 1915.) Price 2s. net.

THIS book is intended "primarily for the use of farmers, gardeners, and agricultural students," and it is hoped that it may assist also "those engaged in teaching and county lecturing." The essentials of a book fulfilling these aims must be that for the student the elementary scientific facts are correctly and clearly stated, and for the farmer and gardener that his understanding of the subject is developed by his attention being directed to general principles while practical help is given. This book falls short of this standard.

The farmer and gardener fail to get the knowledge they want when they are told that "no exact formula" can be given for making Bordeaux mixture, and that "it is always necessary to test the solution before applying, for if too much lime be present it is useless as a fungicide." While the author quotes the titles of recent works on the chemistry of Bordeaux mixture, it seems scarcely possible that he has read them from the account he gives of the chemical composition of Bordeaux mixture. The statement that the preparation of soda-Bordeaux is "somewhat critical," and that since this mixture "possesses no effectual advantage" it can be passed over, will considerably surprise the Irish Department of Agriculture and the numberless farmers who, under their tuition, have saved thousands of acres of potatoes from "blight" by the use of this "soda-Bordeaux" or "Burgundy mixture." The gardener and fruit-grower will not acquiesce in the strange statement that "washes of potassium sulphide" are "very effectual, but too expensive."

The book is well printed and very cheap; it would have been better, however, to have in-

creased its cost by greater care being given to its compilation and by enriching it with good reproductions of photographs of diseased crops.

A First Book of School Gardening. (First Books of Science.) By A. Logan. Pp. vi+151. (London: Macmillan and Co., Ltd., 1915.) Price 1*s.* 6*d.*

THE aim of school gardening in this country is too often merely to teach children to grow cabbages (and other crops) successfully. The author of this little volume, who is well known as a pioneer of school gardening in the north of Scotland, would, in addition, "instruct pupils in the fundamental principles of soil management and plant growth." This double aim is carried out by means of classroom lessons and practical work. "Neither of these types of work, however, has been allowed to encroach upon the other." The book is much more handy in size than the author's previous volume, and is better for being more concise. It will be welcomed by numerous teachers as being exactly what they want.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Modern Universities in China.

EVERYONE knows that the Chinese once led the world in scientific and material development. What may surprise Europeans who are unacquainted with the Far East is that they understood the principles of good engineering design long before our learned men in Britain had investigated such matters.

The arch, beautiful from the scientific as well as the æsthetic point of view, is frequently to be seen in parts of China which have only recently been explored by the white man. The undoubted antiquity of many existing examples proves that this type of structure antedates the arrival of the foreigner. Like printing and gunpowder and many other inventions and discoveries, it was probably of Chinese origin. The bridges, the pagodas, the city walls, and certain details of building construction to be seen in China demonstrate that many centuries ago there were men in that wonderful country who had a complete understanding of some most important principles used in applied science work.

Unfortunately there came a time when classical education alone was in favour. The disasters, political and economic, which have fallen upon the Chinese during their recent history have been in no small measure due to the paralysing effect of their educational system. About thirty years ago a very few people in authority in Peking realised this fact. During the last ten or fifteen years there have been violent changes in the outlook of millions of the people. The old ideas concerning education are almost dead. Western knowledge is in demand.

Many Chinese have entered the universities of Europe, America, and Japan. An effort has also been made to create universities in China. Anyone who has taken an interest in the lives of Oriental students in England must come to the conclusion that it is better to carry Western learning to China, rather than send Eastern students to Europe.

The number of modern universities in China is not great. There are some under the control of the various missionary societies, but of these there is only one (St. John's University, Shanghai) which has any real claim to the title. Other institutions, with praiseworthy ambitions but poor finances, connected with the work of evangelisation are the North China University, the Soochow University, and those known as the Shantung Christian, the Nanking, and the Boone (Wuchang) Universities.

The three which are under entirely secular control are the University of Hong Kong, the Government University of Peking, and the Peiyang University, Tientsin.

An important visitor to any of these centres of learning would come to the conclusion that there is only one of them which is entitled to be ranked with the provincial universities of England. The missionaries have not sufficient funds to obtain the necessary staff and equipment. The Chinese Government place the administration in the hands of Chinese officials, which is almost hopeless. Corruption still exists in high places, despite the changes due to the revolution of 1911.

The University of Hong Kong has already established itself as worthy of British traditions. It commenced its career in 1912, and after three years it has earned the confidence of both Chinese and Europeans in the Far East.

Two events which have recently occurred are significant. President Yuan has provided two thousand dollars per annum for scholarships, tenable by Chinese subjects. A wealthy Chinese, resident for many years in the Straits Settlements, has recently given the University a sum of money equivalent to about 30,000*l.* The conditions of his bequest are curious. He has lent the University half a million dollars, without interest, for twenty-one years.

A few weeks before this offer was received, a citizen of Hong Kong, named Ho Tung, presented the University with one hundred thousand dollars.

In order to show that the local Chinese are sympathetic to, and interested in, this centre of learning, it may be mentioned that a few months ago the writer obtained from them the promise of about one thousand pounds for a cricket pavilion for the Students' Union. This money was raised in a few days, despite the fact that everyone in the colony has given very freely to the various war funds.
